About the Editor-in-Chief

Meyer R. Rosen

CChem, CPC, CChE, CFEI, DABFE, DABFET, FAIC

Meyer R. Rosen is President of Interactive Consulting, Inc. (www.chemicalconsult.com). He is a Thought-Leader and expert in the field of Technical Marketing and multi-industry Technology Transfer Applications including, but not limited to: cosmetics and personal care, applied rheology, applied surface and interfacial chemistry, polymers, organosilicones, professional editing and custom preparation of Mind-Maps® for the organization and presentation of complex information.

Mr. Rosen is a Chartered Chemist and Fellow of the Royal Society of Chemistry (London); a Fellow of the American Institute of Chemists and both a Nationally Certified Professional Chemist and Certified Professional Chemical Engineer. He is a member of the U.S. Society of Cosmetic Chemists (SCC) & the American Institute of Chemical Engineers. Meyer serves as an Advisor for David Smith, Executive Director of the SCC Advisory Committee. He is also Editor for U.S. & Canada and Editor-in-Chief for North and Latin America for Euro Cosmetics Magazine in Germany. Mr. Rosen is Editor of the Delivery System Handbook for Personal Care and Cosmetic Products and Editor-in-Chief of Harry's Cosmeticology, 9th Ed.

Meyer served for six years as the Chief Scientific Advisor and Director of Technical Programming for United Business Media's (UBM) HBA Technical Conferences. He a former Director of the American Institute of Chemists, past

Vice President of the Association of Consulting Chemists and has served on the Scientific Advisory Board of Supply Side West/East: Virgo Publications. Mr. Rosen is also the Founder, Organizer and co-moderator for HBA's Annual International Safety, Regulatory and Certification Symposia.

Acknowledgements

I acknowledge the ongoing sense of calm thoughtfulness of Ben Carr, my wonderful publisher and his confidence and trust in my judgment while providing the special support that has meant so much to me, over the almost three years it has taken to produce the book you are reading today.

I also acknowledge and thank the many authors of this book for their commitment to making this the best Harry's ever written. They have taught me many things by their writings and provided superb networking contacts to people who had the background to write about the areas I saw as needing to be in the book. I am grateful for their growing friendship and relationship and providing me the opportunity to interact with many of the finest minds/people; and their thinking, as well as following my guidelines to achieve our goals.

I am also grateful for the many kind words from my authors and editors who liked my professional editing skills and sharpening them as I went along. Their patience in explaining-in writing-the answers to all of my seemingly endless questions contributed much to my understanding our industry in a way that was far more in depth than I brought to beginning this book. As I said to them, "If you can't explain it to me so I really understand it; then how will our readers understand what you are saying?

I give special thanks to my Editors who took my thoughts and ideas and worked with me to find authors who knew their subjects and could organize and combine the thinking of-the- many to produce a unified-whole. Special thanks also to Navin Geria, Howard Epstein, Chia Chen, Bruce Victor, Bozena Michniak-Kohn, Ruud Overbeek, Manuel Gamez-Garcia, Michael Prencipe, Chuck Warren, Lee Stapleton, Adam Friedman, M.D., Ray Rigoletto, Roger McMullen, Randy Wickett, Martha Tate and so many others who have contributed to this book.

Finally, I wish to thank my friend and colleague, Professor Doctor Johann Wiechers, former President of the IFSCC (International Federation of the Society of Cosmetic Chemists) who unfortunately, unexpectedly and oh-so-quickly passed from this life while on one of his numerous visits to countries around the world. Johann travelled to more countries than I can name, to

encourage and support the IFSCC in its mission to bring beauty and health to the many through his clear thinking, close, objective, ever-questioning and challenging examination of the “science” associated with cosmetics and personal care. Once upon a time, he told me that while travelling the world, he always stayed in the same type of room of his favorite hotel chain because “it always made him feel like he was at home.”

A manager I once had told me that if “I had lemons, I should make lemonade”. And so it was with Johann, who turned the enormous amount of time he spent in travelling to producing an incredible volume of questioning, challenging and probing scientific papers for us to read and think about for years to come.

Wherever you are, Johann, I want you to know that your work and critical thinking approach to cosmetic science has impacted us all-and we miss you greatly.

Dedication

This book is dedicated to my wife Selma, my Soulmate, Committed Listener and Partner in the Journey-of-Life.

She who knows, and reminds me, to put the past in the past in order to open the doorway to the creation of new possibilities and generate new directions for growth in areas we do not know that we do not know.

How remarkable it is When mere words on paper Grow together

Beyond themselves.

Such words as these Are tracks in time.

Memories of a mind Focused

A heart and soul

Ensconced.

MARKETING CONCEPTS TO EMPOWER TECHNICAL PEOPLE

By

Darrin C. Duber-Smith, MS, MBA
Senior Lecturer
Metropolitan State University Denver

ABSTRACT

Marketing is everywhere. Sometimes it's a good thing, since marketing is what drives revenue for the organization. But sometimes it's not so good. Skepticism aside, it's important to understand that marketing is not merely advertising or selling, but the execution of a carefully planned strategy. Marketing is much more than most people think, and much more than just a great story. In today's hypercompetitive, globalized marketplace, product development is largely a function of assessing market needs and delivering goods and services to meet those needs.

Innovation and R&D are very important, especially in the area of cosmetics and personal products. Ultimately, the marketer is the individual responsible for what will and what will not generate revenue for the organization. Thus, underlying consumer needs and the creativity of ingredient innovators, along with pricing, distribution, regulatory issues, and the promotion of products, is a phenomenon known as the *marketing concept*. The vast majority of new products fail, and so the marketer, at the very least, must ensure that the product looks, feels, smells, and works optimally while also generating the right combination of additional marketing-mix decisions. This chapter explores the methods to the "perceived madness" that often vexes even the most experienced product-development professional. It is intended as a guide to the reasoning behind why marketers do what they do.

We note, in passing, that it may seem odd for a technical book like this to begin with a chapter on the "marketing concept." However, as we open the

panorama of a very detailed description of the "ingredients" that lead to successful cosmetic and personal care products, we must first look at the real world where, inevitably, there's both a marketing and technology push competing with the ever-expanding knowledgeable consumer pull for products that work.

1.1.1 THE MAGIC AND MYTHOLOGY OF MARKETING

Marketing is indeed everywhere, and depending on one's role within a particular organization, marketing can represent different things to different people. This can become particularly problematic with regard to product development. What exactly is marketing's role in the development of cosmetic products? The purpose of this chapter is to cut through the confusion and to clarify marketing's role in personal care/cosmetics. First, let's mention a few common myths.

1. "Marketing is selling and advertising."—The first thing a student of marketing should learn is just how untrue this assertion is. Marketing is much, much more than selling and advertising, as it involves product, pricing, distribution, and promotional strategies.
2. "The marketer's job is to sell whatever R&D develops."—The second thing a student of marketing learns is that goods and services, in this age of hypercompetition, must be driven by assessing and meeting consumer needs. Goods and services that are not need-based seldom succeed in the marketplace.
3. "My new product has a great chance of succeeding."—Actually, the vast majority of new products (about 90%) fail to meet expectations and are deleted from the company's product mix within a few years.

4. "Word of mouth is a marketing activity."—It is not a marketing activity, but rather a result of our communications efforts. When someone says that most of their marketing is word-of-mouth-based, especially in the age of Internet, be very concerned.
5. "Marketing is about telling consumers what they want to hear."—A marketer must never mislead the consumer. If we overpromise and underdeliver we ultimately lose customers, who are very expensive to acquire. These unhappy people then tweet, blog, Yelp!, and otherwise report on the company's malfeasance. This is not to underestimate the power that media, NGOs, government, competitors, supply-chain members, and other stakeholders have in keeping companies honest.

Indeed these are only a few of the most common misperceptions that both newbies and experienced product developers have when they think of marketing. So what is the true function of marketing?

All organizations have multiple functions within the company's hierarchy. General management, HR, finance, accounting, production, operations, R&D, and IT are just some of these functions. Each has its own primary purpose. Finance manages cash flow and investments, accounting keeps records, HR manages personnel, R&D develops what might be the next big thing, *etc.* The primary function of marketing then, if we must boil it all down to one thing, is Revenue. Marketers must drive revenue or else the organization cannot exist, and to do so effectively, we must first discover what it is that consumers want and need. In some cases, a concept may be so new that consumers may not even be aware they have a need for it.

1.1.2 THE MARKETING CONCEPT

Academic professionals, in their never-ending quest for professional credibility, will often argue over things that seem silly to the rest of us. One of these arguments concerns the difference, if one actually exists, between a "want" and a "need." For our purposes this argument is spurious. Different groups of people have different priorities, and so the idea of what someone wants versus what someone really needs can be debated until the cows come home. The point of the "Marketing Concept" is that we develop no new products unless we can prove that a large enough group of people will buy them. It's as simple as that, but this means that product development is most often driven by marketing analysis and not by innovation, an assertion that does not traditionally sit very well with the

science crowd.

The reality is that the world of marketing is not at all black and white, and that product development is really a carefully planned and effectively implemented process that involves interplay between the folks whose job it is to study consumers (marketing) and the technical folks whose job it is to make a highly effective hair or skin care product. So let us now delve into the new product-development process with a particular focus on developing a strategic marketing plan.

1.1.3 ASSESSING THE MARKETING ENVIRONMENT

New product development begins with an idea. Ideas can come from many places—customers, competitors, employees, supply chain members, universities, and of course the research and development efforts of our cosmetic chemists. In many cases, ideas come from industries that have nothing to do with cosmetics or personal care. An interesting example is the use of information from the carpet industry by hair care product developers (fibers are fibers, after all). The concept of Open Innovation, described elsewhere in this book under Sustainability and EcoResponsibility, describes this process of ideation.

Many ideas are derived from formal brainstorming sessions, usually led by a high-level marketer (i.e., a Technical Marketing Expert) and involves members of all of these groups. Ideas that are initially thought to be feasible undergo “proof of concept” testing wherein relevant parties are interviewed, answer surveys, or participate in focus groups. Here we must prove that the concept *might* work *before* we conduct further analysis; and assessing consumer needs are a huge part of this process.

The next step is to conduct an analysis of the current business environment. This consists of both internal factors, which are controllable by the organization, as well as external factors, which are out of the marketer’s control. The resulting situation analysis (sometimes called business analysis), gives us all of the information that we need to develop a SWOT summary use in decision-making and risk reduction. The analysis itself is a very objective exercise, and as such, opinions are not needed until these can all be summarized as a series of Strengths, Weaknesses, Opportunities, and Threats. The first two areas are derived from the internal factors and the latter two from the external factors.

Internal factors include a full analysis of all the functional areas within an organization that could affect marketing strategy. This includes pretty much

everyone, and a good marketing plan is a cross-functional effort. Involving all relevant aspects of the organization makes for a better-quality plan, and more buy-in among key players as to how the organization is going to achieve its objectives. It all begins with the organizational mission, a statement of scope and purpose, and includes everything that is under the organization's internal control. Finance, IT, current marketing efforts, and R&D are among these, and strengths and weaknesses are what emerges from such analysis.

External factors include the areas that might present opportunities and/or threats to the organization and its attempts to develop and market products that people actually need. An analysis of the industries, consumers, and other factors like the economy and competition is an absolutely crucial part of making the right stuff for the right people. Market segmentation analysis is used—a process whereby a market is broken down into individual consumer segments, each of whose members have many important characteristics in common. Demographics such as age, gender, and income are combined with psychographics (behaviors and attitudes derived from surveys and focus groups) and geographics to form well-defined market segments. Once marketers can understand the people who comprise a particular segment, they are better able to meet their needs through tailoring the right combination of what we call the Four P's of Marketing or the Marketing Mix. This area may require exhaustive marketing research in the form of surveys, focus groups, and other methodologies.

1.1.4 THE FOUR P'S

Although a few P's have been added by overzealous academics over the years, it is really only necessary to understand the "Original Four." Once the marketer has conducted a situation analysis and its companion SWOT summary, it is time to develop the marketing program, the foundation of which is Product, Price, Place, and Promotion strategies.

Product strategy is where the real work between marketing and R&D comes into play. The decision to use certified organic or natural ingredients instead of synthetic ingredients, for example, might be driven by marketing, but the reality of working with these ingredients and still being able to manufacture an excellent personal care product is another story. Product-development chemists and the folks working on the manufacturing end of things might have constraints that the marketer may not fully understand. However, it is the marketer whose job it is to monitor the marketplace and assess market needs. Teamwork and cooperation here are of paramount importance, and this is often where new products fail when cooperation falls below the bar-of-success. The wrong product is made for the wrong target market oftentimes because marketing and other organizational entities won't cooperate, and thus function too independently. Product strategy is the foundation of marketing. The team must decide on the ingredients, the positioning (different from competitors), packaging, branding, and other strategic considerations before pricing.

Pricing the product depends on several factors. First, the cost must be considered, including variable costs (cost of goods sold), as well as fixed costs such as general/administrative and sales/marketing expenses. These costs must be covered, but that's not all. On the demand side of the equation, the marketer must look at the prices of competitive and substitute offerings as well as what prices consumers might be willing to pay. A competitive product and market analysis can run in the several hundreds of pages and such reports may costs tens of thousands of dollars. Unless the marketer decides to sell the product directly to the consumer through the Internet, TV, direct mail, or some other channel, any pricing strategy must also consider both wholesalers (distributors) and retailers. The former intermediary often takes 10% or more of the retail price and the retailer can take as much as 50%. What is left over after cost and channel considerations is profit. This is a lot to consider, and the marketer has dozens of pricing strategies from which to choose.

Placing the product involves distribution decisions and choosing a mix of retail channels to sell it. Should the product be distributed exclusively, selectively, or intensively? Should it be found in higher-end natural products stores, or should it be sold in Walmart and through the grocery channel? Such decisions should not be taken lightly, and they depend fully on both the product and pricing strategies.

Promotion is what most people think of as "marketing communication." Marketers have a myriad of promotional strategies and tactics to choose from and must find an acceptable mix under the marketing budget. Advertising, public relations, direct marketing, sales promotion, and personal selling are all important elements of marketing communication. Much of this communication is moving toward the digital medium, but it is important to realize that the majority of marketing is conducted through what we would call more traditional media such as TV, radio, magazines, newspapers, outdoor and indoor signage, *etc.* The advent of social media and the proliferation of digital advertising have made the marketer's job far more difficult in recent times; but, on the bright side, they have made the control, evaluation, and quantification of marketing activities much easier. Marketers must engage in both "push" marketing to encourage distributors and retailers to carry the product, as well as "pull" marketing to inform consumers what the product is, what it can do (claims), and where it is available. This can be rather expensive as you might imagine, but without it, the product has no chance whatsoever of succeeding.

Before we look at the remaining steps in the product-development process,

something should be said about product claims. Historically the marketing of ingredients with great stories behind them (traditional use, exotic derivation, etc.) has forced marketers to make product claims for what the product is supposed to do, and unfortunately many product developers fail to include an efficacious amount of the ingredient, thus rendering the product ineffective—a phenomenon known as "dusting." The FDA is watching ever more closely, and manufacturers are under increasing pressure to make products that really work. Not only this, but the nature of claims (especially with the FDA's mandate to eliminate false or misleading structure-function claims) is of critical importance to providing proper information to the consumer looking for a solution to a problem. The natural and organic ingredients business has been plagued by this, but mainstream cosmetic and personal care also suffer from this syndrome. When products fail to meet expectations and marketers make promises that product developers cannot keep, the brand and ultimately the entire organization suffer.

1.1.5 DEVELOPMENT, PROTOTYPES, TESTING, AND COMMERCIALIZATION

Once a business analysis has been conducted, preferably in the form of a written strategic marketing plan, it is important for the product-development team to develop a prototype, or in the case of personal care, a final formula for testing purposes. Obviously shelf aging stability, bacterial contamination, and other testing are conducted until the results are satisfactory and any necessary changes are made to the formula to make it robust under foreseeable conditions. Even if the actives have been clinically tested, it is a good idea to test the product itself so that any claims made can be substantiated. Additional market research may also be conducted at this stage if the picture is still incomplete. Once the formula has been "finalized," labels, containers, applicators, and all other considerations should be considered since packaging is such an important part of the consumer experience in this industry. In this regard, Part 1 of this book also includes a detailed description of how attractive packaging is designed. When several mockups have been made with finished product inside, it's time for employees, suppliers, friends, family, and others who are closest to the organization to get an initial feel for the finished product.

In many industries, a product is market tested before it is released to the broader population. This is often done in specific stores or regions of the

country. Such test marketing can tip off the competition, but it may be important to reduce the risk of utter failure by doing a bit of test marketing. The personal care industry admittedly doesn't do much of this, but it is an important step to mention in any interpretation of the new product-development process. Hopefully, the organization's finance function has liberated enough cash flow to produce large volumes of the product and support it with the proper marketing efforts. Since marketing planning is always time-bound, the period of evaluation will culminate in an actual evaluation of what happened. Did the product introduction work? Why or why not? What should we have done differently?

Table 2 ***The Green Marketing New Product-Development Process***

Step 2 Concept Testing
Step 3 Business Analysis/Marketing Planning
Step 4 Product Development
Step 5 Market Testing
Step 6 Commercialization
Step 7 Evaluation of Market Results

1.1.6 THE TRUTH ABOUT INNOVATION

Here is an important question to ponder. Just because an ingredient or a product is "new," does that make it "innovative"? It seems that this word has been thrown around quite a bit and has lost much of its meaning, similar to the way that social media, and Facebook in particular, have somewhat diluted the word "friend." And this begs the question: Are ingredients truly innovative, or is this just a bedtime story that product developers tell themselves so that they have a better reason to rise and shine in the morning? Just because a new botanical or ingredient blend is new or popular doesn't necessarily mean that it is innovative in any real sense. Let's explore this rather controversial assertion further.

The term "innovation" has been used to describe all kinds of underwhelming product developments, and the popular understanding of the term is that it means "new." I think we can all agree that the telegraph, automobile, light bulb, radio, television, computer, and smartphone were all groundbreaking innovations; but what about each iteration of the iPhone? Is a new emollient truly innovative? What about a new natural preservative? Or, a new, naturally derived active ingredient?

Innovation and Product Development

Product Development is one of the author's favorite university courses to teach, and in this important class we learn that there are three forms of innovation.

1. A **continuous innovation** describes a new product that requires almost no change in consumer behavior, and so it represents very minor changes in an existing product type. An example of this would be an existing hand lotion product that features a new nonactive ingredient, or if you prefer a technological example, each and every iteration of the iPhone would be continuous. Many experts do not consider a continuous innovation to be very innovative at all.
2. A **dynamically continuous innovation** involves a major change in a minor behavior or a minor change in a major behavior. An example would be a hand lotion (either an existing product or a new one) that features an entirely new way of dispensing the liquid, such as moving from a jar to a pump. Or technologically speaking, it's the difference between a tablet and a laptop.
3. A **discontinuous innovation** can be very disruptive to the industry. An example in personal care would be a product (or a newly discovered ingredient) that has an entirely new market application, such as hair regrowth. The decade-old advent of skin and hair care products in the form of ingestible nutritional supplements may have been the last true discontinuous innovation in our sector. In tech terms, the inventions mentioned earlier in the article "Which Ones?" would qualify as discontinuous innovations.

In most cases, it's not really the ingredients that are innovative, but the finished product. And in every case, it's always the degree of consumer behavioral change required, and not the ingredient/product itself, that determines the type of innovation. It may sound academic, but what happens is that people in general become desensitized to words they hear all the time such as "innovative," and when they are underwhelmed by what they see, it serves to further numb the target market to the marketing message. I think we can all agree now that the vast majority of new products are continuous innovations. The really groundbreaking product, featuring an entirely new ingredient with an entirely new application, can only be introduced once. After that, successive products will be dynamically continuous or continuous innovations. As such, in almost all cases, "hot" ingredients are merely popular, and not really innovative.

The Patent Process

Now let's look at the patent process. In order to qualify for a patent in the U.S., an invention must be novel, involve an inventive step not obvious to a skilled person, and have an industrial application. If approved, the patent is exclusive for 20 years. Patents are awarded in cosmetic and personal care products all of the time, mostly in the form of process and composition of matter inventions. The vast majority of these do not require changes in consumer behavior, and so they cannot be considered innovations in any respect, and in too many cases the changes are things the consumer doesn't even notice. It's no small wonder then that many observers, including the author, believe that patents are far too easy to obtain and that this is actually very bad for innovation.

Unfortunately, this is often lost on most industry people (who have never taken business classes), but it is very basic science to those of us who have. We learn that new products (which fail 80–90% of the time) should be need-driven in almost all cases (excepting the area of needs that consumers didn't know they had in the first place, which is rare). The firm's job is to address, and in many cases exceed, expectations in meeting the market need while differentiating their offerings from competitive and substitute products. This attempt at differentiation generally results in a whole heck of a lot of noninnovation, some continuous innovation, and an occasional dynamically continuous innovation, but rarely does it result in something that disrupts the industry.

Nevertheless, marketers and media alike will continue to push "the next big thing" as manufacturers look for the next incredible ingredient and retailers tailor their product mix to meet the demands of their customer base. The author will take the road less traveled here and remind everyone that *new market applications* are what spawns innovation in the personal care world, and not necessarily a new ingredient that meets an existing need. So let's dispense with the hype and begin talking about ingredients and products in terms of how consumers view them rather than "innovations" that do not matter to the marketplace. Indeed market applications are crucial to justifying the use of certain ingredients as well as the development and commercialization of the products themselves.

1.1.7 THE MISSING LINKS

Our discussion has obviously been rather academic. The reality is that many product-development teams, not unlike groups of all kinds, are very dysfunctional. Obviously, we know that this perfect world exists only in the

minds of academics, and that the reality of product management is rather messy. Yet, as marketing professionals we must agree on a foundation of theoretical concepts and best practices so that we know how to approach each and every unique situation. Indeed the "science of marketing" must be applied as a basic framework for achieving organizational objectives.

In today's hypercompetitive marketing environment, three areas in particular must be better addressed by corporate leaders if organizations are to increase the chances of their products' success:

1. More cooperation is needed among all functional areas of product development, including marketing, R&D, and manufacturing, for a more seamless product introduction. Today's company needs an interdepartmental understanding that products must be based on needs; that innovations come from R&D and can be incorporated into this need set, or in some rare instances, consumers might discover needs they didn't know they had; and that all of this has to be feasible for manufacturing.
2. More cross-functional employees with multiple degrees would help matters vastly. It is entirely conceivable that members of the staff can have both marketing (business) degrees and chemistry (science) degrees. Dual-degree programs are rather common in today's university environment and a second degree might only require one extra year of education. In addition, a person who has a BS-Chemistry can easily get an MBA or an MS-Marketing with an additional one or two years of education. Why must it always be one or the other? It is our observation that individuals who rise in companies the best are those who have both marketing and technical experience and background.
3. Over the past decades, companies have vastly reduced the amount of money they spend training existing employees, hoping that the universities have done their job. Don't bet on it! Universities are great with theory, but application of theoretical concepts leaves a lot to be desired, and some of this burden must be reappropriated by the organizations themselves. Hire people with great aptitude and basic knowledge, and then train the heck out of them.

Marketing is really everyone's responsibility. Inadequate efforts led by a failure to understand and apply the principles of marketing will almost guarantee product failure in an environment that sees 80–90% of new products languish on the shelves, slated for eventual deletion. In-depth business analysis and market testing, anchored by intensive market research, will greatly reduce a marketer's

risk and will give the scientist more confidence that his/her creation will be a hit with consumers. Flying blind in an age of radar and GPS technology is ill advised even though it may be an exhilarating experience. *A failure to recognize and apply the Marketing Concept at all levels of the organization is akin to flying blind, and there is no glory in product failure.*

PART 1.2

CREATING THE RIGHT FRAGRANCE FOR YOUR PERSONAL CARE PRODUCT

Jill B. Costa, Ph.D.

Bell Flavors and Fragrances

500 Academy Drive

Northbrook, IL 60062

jcosta@bellff.com

1-800-323-4387

ABSTRACT

It has been said that no matter how good the technology in the bottle, when the consumer opens it, if it doesn't smell good, look good, feel good, and rub in well, then they won't buy it. As such, fragrances play an incredibly important role in the presentation of a cosmetic or personal care product.

Fragrances are a complex mixture of natural and synthetic materials designed to cover the malodor of a product base, make a cosmetic and personal care product smell appealing, and most importantly, reinforce the product's benefits to the consumer. They are used in nearly every product type and category!

The overall performance of a fragrance in a product is therefore critical to its commercial success. While products are typically developed with technology that works and claims are made as to what to expect, it is common practice for product developers to approach fragrance houses for advice as well as for recommendations as to what to purchase that will enhance the overall presentation of the product and achieve the goals of the brand.

This unique chapter is essentially divided into two parts. The first provides guidance and a general understanding of what, *and how*, to request product and services from a fragrance house. It also describes what can and should be expected of the fragrance house.

The chapter then goes into detail about the composition of fragrances and introduces the reader to the detailed thinking and tools that describe how a fragrance is composed by the Perfumer, and the best way to evaluate the performance of the fragrance in a product. This approach is key to choosing a successful fragrance. The chapter also contains discussion of the impact of EU (European Union) regulations on fragrance formulating and labeling relative to alleged allergens. Finally, it concludes with a focus on three important points: 1) a comprehensive discussion of the many different types of fragrances; 2) insight into making the best choice of asking about what the product formulator and marketer want to achieve; and 3) tips on how to best label these emotive actives.

1.2.1 THE FRAGRANCE HOUSE

AS the phrase implies, a fragrance house specializes *solely* in the creation of fragrances. Most fragrance houses are structured in a similar way with respect to personnel and project flow. Usually, a Salesperson interacts with the cosmetic chemist to obtain information about the potential project. The Salesperson may ask the cosmetic chemist a variety of questions to help define potential fragrances for their products. For example, questions would be asked about the type of products in which the fragrance will be used; the type of fragrance or odor character desired; and any benchmarks or olfactive targets to consider; information would be required about the brand and target market, the desired price point of the fragrance, or the dosage of fragrance in the product. Other areas of interest will be the price per unit, regulatory considerations, and the expected volume of the fragrance to be sold per year if the project launches. This information is provided to the **Sales Management team** in the fragrance house to determine whether enough information has been given to assign a priority to the project.

Overall decisions are typically made using the financials of the project and the relationship of the fragrance house with the requesting company. If the project passes review, it is passed to the **Evaluation Department** to determine whether the fragrance requested already exists in the “library” (fragrances already created and approved by an Evaluator, but not sold to any company) at the fragrance house, or whether the request needs an investment of a perfumer to create a fragrance to fulfill the request. If suitable types of fragrances exist in the fragrance house's library, these will be chosen by the Evaluator, compounded, evaluated in a product base, and sampled to the cosmetic chemist for review. If no suitable fragrance exists internally, a Perfumer or Perfumers will have to create a fragrance for the request. The new fragrance creations will be reviewed by an Evaluator iteratively in accordance with the protocol described above, until they meet the requirements of the request.

The Perfumer–Evaluator team is a very important part of the fragrance house. An Evaluator is much like a food critic, or a golf caddy, whereas the Perfumer is much like a chef, or a pro golfer. Part of the role of an Evaluator is to understand the cosmetic chemist's request and extrapolate the request into an

olfactive structure that a Perfumer can create against. Evaluators also have a good understanding of current olfactive trends in their specialized product areas, and will use this information to guide the Perfumer to ensure the result is “on-trend” in odor, but is also pleasing overall. Evaluators don't tell Perfumers which specific materials to use, but rather what odor impressions or characters should exist in a creation and whether they are on-trend as per the Evaluator's understanding of their specific area of expertise. Evaluators provide a sounding board for the Perfumer to discuss olfactive directions and act as an impartial critique of a creation, much like a caddy provides a technical view of the shot at hand. Using the feedback and input of the Evaluators, Perfumers are free to use the materials that would be appropriate for the product type but also meet the regulatory restrictions of the particular geographical targets for the product. Due to the broad knowledge of the olfactive market involved, Evaluators generally specialize in fields such as Air Care, Household Care, or Personal Care. In the case of cosmetics and personal care we are primarily concerned with the evaluation points of personal care products that are used on skin and hair.

The Perfumer is a very specialized position. Most Perfumers have been trained by experienced Perfumers in an apprenticeship-type job training that takes from five to ten years. Many start as Fragrance Compounders and then move up to Perfumer's Assistant to Junior Perfumer and then Perfumer. During this time, a potential Perfumer studies and understands the general structures of classic and current fragrances as well as developing their own new creations. A Perfumer has committed to “olfactive-memory” up to 3,000 individual fragrance raw materials during their training. The majority of the required talent and creativity of the perfumer is in understanding how combinations, or “recipes” or “accords” of these materials interact with each other in a product base to form beautiful fragrance compositions that will meet the requirements of a request. The Perfumer is also expected to understand the current regulatory landscape and to know general stability parameters of the individual fragrance components in a variety of product bases such as shampoo, bodywash, conditioners, lotions, and styling gels so that the fragrances will be likely to perform as intended. Additional support is given to the Perfumer–Evaluator teams by the fragrance house's Applications department, which incorporates fragrances into product bases. The bases may be those supplied by the requesting company for a specific project, or may be a “house-base” developed by cosmetic chemists within the fragrance house.

An additional part of the Applications department's responsibility is to handle

any requests for stability testing and to create various product prototypes needed for Sales, Evaluation, and Perfumery. Other key teams that support Perfumery and Evaluation but have different duties include Marketing, which interacts heavily with Evaluation for defining overall trends and providing other marketing support.

The **Analytical Department**, extracts and analyzes the composition of specific fragrances of interest on the market that have not been created by the fragrance house in order to provide current “competitive” information to the Perfumery Department. The **Regulatory Department** provides the final determination as to whether a submitted fragrance meets all the requirements necessary for the request, and their information is invaluable not only to the Perfumer for a creative project, but also to the Evaluation department in the case of a fragrance chosen for a project from the library.

The actual creation of a new fragrance by a Perfumer generally occurs in front of a computer with a specialized software system that has a list of materials available to a Perfumer, and the final formula based on a weight or volume percent is quite like a recipe for baking or cooking. As the formulas are optimized over the Evaluation process, they are streamlined to include only the necessary materials at the proportions required for the performance of the fragrance. The Perfumer can recall the odor of several thousand materials and will first develop the beginnings of the fragrance formula in their “mind's-nose,” or they will start with a part of a formula that they have worked on in the past. The Perfumer may start a new project by putting together a fragrance formula that is about 85–90% complete and use the materials they are sure they want to use, in a ratio that they know, or can reasonably be sure will be appropriate for the request at hand. This methodology is highly useful in order to streamline the required iterative creative process. This “partial fragrance” is compounded by the Fragrance Compounder and returned to the Perfumer. If it is what the Perfumer was expecting, the Perfumer may ask the Applications department to apply the fragrance to a product base.

After evaluation in product base by the Perfumer and/or the Evaluator, the Perfumer may create several trials to complete the last 10–15% of the fragrance composition. Each trial is a specific twist on the fragrance that uses materials whose effects are more difficult to predict, or some untried out-of-the-box ideas that may or may not work well. These trials are also applied to the choice of product base, and these choices are evaluated and compared to each other and to the cosmetic chemist's request by the Perfumer and Evaluator. One or more of

the trials may go forward, or the Evaluator may ask the Perfumer to continue to further develop the concept and create more trials. This process is repeated until there are several fragrances ready to submit to the cosmetic chemist.

Usually from five to 15 trials are needed by a Perfumer to create a new fragrance that is deemed worthy to show to a cosmetic chemist. Depending on the project, several Perfumers may be assigned and then the Evaluator will make a selection of the chosen fragrances across multiple perfumers to give to the Salesperson to show to the cosmetic chemist in order to ensure each submitted fragrance is different enough to stand on its own. The cosmetic chemist will also be informed that the entire chosen range of fragrances is appropriate for his/her request. The fragrances that are completed, technically acceptable, and olfactively sound *but are not chosen by the Evaluator* are placed into the fragrance house's library for possible future use.

As a result of this process, a Fragrance House's library may have tens of thousands of finished formulas available for internal use. This is why most creative fragrance houses do not offer a “catalog” of fragrances . . . there are simply too many to catalog, they are too difficult to describe thoroughly, and since they have to be designed for a specific product type (for both regulatory and technical reasons described elsewhere in this chapter), it would not be a useful exercise.

If a Perfumer is unable to smell due to a cold or other reason, creative work continues since the formulations created by the Perfumer on the computer can be compounded and then smelled by the Evaluators or other Perfumers in a group setting. As the cosmetic chemist's request is always used as the criterion for being chosen, the team members can provide feedback to the Perfumers to help them improve the fragrance until they are able to smell again. When smelling for a living, the Perfumers and Evaluators learn to take very shallow breaths and to clear their airways in between evaluations. Most professional Perfumers and Evaluators simply space their smelling sessions strategically throughout the day rather than pollute their noses with strong-smelling materials such as coffee beans. After the Evaluator and Perfumer decide on the fragrance selection to be offered, the Salesperson shows the chosen fragrances to the cosmetic chemist. After some form of evaluation, the chemist should give feedback to the Salesperson on each of the submissions. This feedback goes to the Evaluator–Perfumer team and helps them for future requests, or helps to optimize a specific fragrance for a current request. The feedback can be about the fragrance's performance in the product base, the overall odor character, or any comment

about how well the fragrance fulfilled the request. All feedback is helpful to the fragrance house to understand their customer (the cosmetic chemist).

Once a fragrance is chosen by a cosmetic chemist and the decision is made to purchase the fragrance from the fragrance house, the Perfumer's formula is activated into the fragrance house's Production system, and is removed from the fragrance house's library so that it will not be used again for other customers. The Perfumery department sends a sample of the fragrance to be purchased to the Production's QC Department to be used as a standard. The flash point, refractive index, general color range, and specific gravity are already known from the trial samples sent to the cosmetic chemist. The QC chemists are trained to compare the standard to their productions via a “triangle test” to determine if the odor is comparable to the standard. (Each panelist is presented with two samples of the control and one sample of the test material, or two samples of the test material and one sample of the control, and they are asked to locate the “odd” sample; the results are statistically analyzed to determine whether the samples are different or not.) In addition, the refractive index, specific gravity, and color specs are compared to those that exist for each formula.

1.2.2 FRAGRANCE MATERIALS

Individual fragrance raw materials may be natural or synthetic. Each of these materials is carefully characterized by RIFM (Research Institute for Fragrance Materials—http://www.RIFM.org) and is regulated by IFRA (International Fragrance Association—http://www.ifranaorg). RIFM conducts safety and environmental studies on the fragrance raw materials and maintains the “master list” of materials that are permitted as fragrance materials. IFRA regulates the amount of each material that can be used in a fragrance and ultimately in a finished cosmetic product, for specific product categories, which is delineated in the QRA (Quantitative Risk Assessment) document. There are currently 11 product categories addressed in the IFRA regulations. They range from lip care to shampoos to wipes to candles. These categories are based on the expected dosage of a fragrance material that the public is expected to be exposed to and depends on the type of product used. It is useful for the cosmetic chemist to know in which of the IFRA categories their product falls, particularly when requesting paperwork from the fragrance house. IFRA actively educates the public as well as the chemist about the safety, history, production, creation, and use of fragrances via video and statements on their website and through social

media.

Natural fragrance materials are most often categorized as *essential oils*, *absolutes*, *concretes*, or *natural isolates*. **Essential oils** are usually obtained by steam distillation of the part of the plant that contains the essential oil. During the distillation process, the essential oil floats on the water. It is then separated from the water and any remaining water is removed. The odor of the essential oil is compared to standards for composition and overall odor. In the case of citrus oils, the essential oil is obtained by squeezing the peels of the fruits. As with other plants, the citrus oil is removed from any water that may be present after squeezing. Essential oils generally are relatively expensive versus a synthetic material (except, depending on the year, citrus oils—since the citrus industry produces a large amount of food products, and the peels are byproducts that can be used for the fragrance industry).

Essential oils are normally used in a standard fragrance (one that is not designed to be all natural) at levels from ~1 to 20%, while the remainder of the fragrance is synthetic. Essential oils add complexity and a certain "naturalness" to a fragrance, but they also add cost, as their pricing is dependent upon supply. These oils can fluctuate in cost dramatically depending on yield, political climate of the producing country, and even time of year. Weather disasters in citrus regions can create serious supply issues.

Concretes are obtained by the extraction of a plant using a hydrophobic solvent. This approach yields a product that is an essential oil mixed with waxes and any other hydrophobic material soluble in the solvent employed. A hydrophobic solvent is removed to yield the **concrete**. Further extraction of the concrete with ethyl alcohol and removal of the alcohol yields an **absolute**, which is the essential oil that contains any other materials soluble in ethyl alcohol. The waxes and other ethyl alcohol-insoluble materials are then removed, yielding a product that is completely soluble in ethyl alcohol. Absolutes of extremely faithful odor quality may also be obtained by supercritical carbon dioxide extractions of the plant as well. Concretes and absolutes are very expensive and are used as "touch" ingredients in fragrances. This means that in a fragrance they may each range in concentration from 0.001 to 0.100%. Even at these low levels they add significant cost, but they also add significant "odor value." If they are removed their removal is quite noticeable, as the fragrance would smell less "rich" and less "extravagant." Most of the time, these materials are only used in expensive, fine fragrances and very high-end creams and lotions.

Natural isolates are obtained by varying physical means from essential oils by

crystallization (such as crystallizing menthol out of peppermint oil), or fractional distillation, where an essential oil is distilled using heat and the various raw materials are isolated by means of separation, employing their differing boiling points. There are no chemical transformations made on natural isolates—they are merely components of essential oils that have been removed from the intact essential oil. These materials are generally also expensive since one must first obtain the essential oil, then put in some additional amount of work to obtain the isolate (usually by distillation). The use of these materials is discussed later in this chapter.

Synthetic fragrance materials are made by chemical reactions on starting materials. Many synthetic materials are derived from crude sulfate turpentine chemistry (as an example, see http://www.renessenz.com/site/production). Some are derived from petroleum products, and yet others are made starting from complex molecules isolated from plants. The majority of the commonly used fragrance materials are synthetic and form the framework of the fragrance. Advantages of synthetic materials are that they are typically very completely characterized by the supplier, are in plentiful supply, are relatively stable in cost, and are not seasonally dependent. There are more varied odor characters available in synthetic ingredients, and they are currently what consumers are used to smelling in their products.

Botanic materials are different than fragrance materials in that they are typically not used to impart an odor to the finished product but are used for marketing or performance reasons. These materials may be derived from any part of the plant, even those parts of individual plants that are not used to provide an essential oil (which vary per plant), with almost any appropriate solvent. Botanics are regulated on the cosmetic product's label by the PCPC (Personal Care Product Council, formerly the CTFA—http://www.personalcarecouncil.org/).

1.2.3 WHAT IS A FRAGRANCE COMPOSITION?

As we have stated earlier, fragrances are complex, well-balanced mixtures of individual natural and synthetic fragrance materials. A fragrance is perceived as an entity with its own aesthetic identity. The unique characteristics of each of the individual fragrance ingredients stay in the background and contribute to the fragrance as a whole without being suppressed.

The identity of the ingredients used in fragrances varies depending on the

desired odor profile, final product category, and form. For example, this would include but not be limited to oil-in-water emulsions or a transparent micellar solution. Fragrance houses and perfumers study which individual fragrance materials perform the best in each product type. They use this experience to combine the ingredients to create complex fragrances that should perform well in that product type. *Since the performance is primarily a qualitative assessment, consultation with an experienced fragrance house is essential if product developers are committed to producing a final acceptable product presentation.* It is also of importance to recognize early on that each product has a number of key points of evaluation in the use-cycle and that these must be determined and evaluated for optimal overall use results.

The creation of a fragrance also differs based on the desired effect upon the consumer. For example, technology is available to provide a refreshing burst of fragrance in use, or long-lasting soothing type or even multiple fragrance notes, delivered over time as the consumer wears it. Perfumers also understand which materials and overall odor characters can create an emotional response such as refreshment or soothing, as well as many other types of emotions and product properties. They are skilled at creating their fragrances to optimize the multiple connotations of these effects. Much work has been done in this area, as the impingement of fragrance molecules on the sensors in the nose is directly transmitted to the brain. The mechanisms of the relationship between pleasant and unpleasant, stimulating or calming, and other effects, have been well studied and will be presented in the Nose section below.

In view of the above discussion, one can see, for example, the actual fragrance materials and the balance of those materials used in a fresh green rosy musky fragrance (intended for use in a soft deluxe facial crème) will probably differ dramatically from a fresh green rosy musky fragrance designed for use in a shampoo, but they actually may smell quite similar.

1.2.4 CREATION / CONSTRUCTION OF FRAGRANCES

a. Top, Middle, and Base Notes

Fragrances are composed of a blend of top notes, middle notes, and base notes (“notes” may be used interchangeably with "character"), a blend that is often represented as a pyramid as seen in Figure 1. A “note” or “accord” is defined as a type of odor character —almost like a mini-fragrance in itself. For example, a

"fresh rose" (perhaps versus a "dark red rose") will likely be composed of two to 20 individual fragrance materials, each of which will contribute a facet to the overall "note." For example, some of the fragrance materials will be grassy green in character and provide freshness, while other materials will be rosy for the overall character. Yet others may add a deep wet or dewy effect to that accord.

Figure 1 Fragrance Pyramid

To make the fragrance, several accords or character notes are combined in different ratios. Fragrance houses will provide on request the “breakdown” of the identity of the top, middle, and base-note characters using an industry standard known as a pyramid—type diagram or something equivalent. It should be emphasized that listed notes or characters are not usually single materials, but are the qualitative perceivable odor characters that the Perfumers and Evaluators have used to provide the overall effect. While artificial “mechanical noses” are being experimented with, at this time the perfumer's process remains a creative one. Such artificial noses are being used as a limited quality-control method in a production setting.

Top Notes are materials and olfactive characters that are immediately perceivable and tend to be the most volatile (volatility is explained in detail in the next section) materials in the composition. Citrus, green, marine, ozone, and some lighter fruity notes are often in the top notes of a fragrance.

The **Middle Notes** are the “Coeur”—the French word for “heart”—of the fragrance. These notes are often the most characteristic and recognizable part of the entire composition. Some florals, sweet, gourmand (edible), and some deeper fruity notes and lighter woody notes can be middle notes.

The formulation of a fragrance is truly a creative process. There is no quality control on fragrance notes during the process. The Evaluators have their own vocabulary, and that is what is taken to be the “standard.” This subjective approach may not be quantitative, but *creativity demands a right-brain approach*.

The **Base Notes** of a fragrance are the longest-lasting part of the fragrance and tend to be the least volatile (i.e., have the lowest vapor pressure) of the notes in a composition. They act to support, round, and extend the richness of a fragrance. The base notes tend to be the most expensive part of a fragrance, so having them is important in order to ensure that a fragrance does not smell “cheap” or “thin.” Musks, woody notes, amber (rich sweet nonedible) notes, and deep heavy floral notes tend to be in the base note.

b. Fragrance Characters

Fragrances are designed by a Perfumer to have a specific odor character overall and to perform well with a defined character at discrete times in the product-use cycle. We use the term “character” as a term of art in this context and distinguish the term “characteristics” as being more consistent with measurable physical properties. By character, we mean the individual odor components involved in making the fragrance. The variation of the intended characters in different product types is what makes perfumery such a high art—extremely difficult and hard to predict. However, understanding the general processes at play can help a cosmetic chemist and marketing manager decide if a fragrance is appropriate for a product or not.

1.2.5 INTERACTION OF FRAGRANCE MATERIALS WITH PRODUCT BASES

A fragrance may smell one way out of the bottle but after being added to the product base it may smell differently in unexpected ways. Product bases in this chapter are generally those that are applied to skin or hair. For example, a facial crème generally is an oil-in-water emulsion, while a shampoo or body wash is a micellar solution and a bath oil is a solution of fragrance in oils with additives.

A review of how fragrances are able to be perceived is useful to help understand changes in fragrance character that may be seen after a fragrance is applied to a product.

There are three major hurdles that have to be surmounted for a fragrance material to be smelled, and therefore for a fragrance to be perceived as intended by the Perfumer. Each hurdle will be discussed in detail and summarized below.

First, Fragrance components need to be *volatilized* into the air in order to enter the nose and interact with the nasal sensors and be perceived by the brain. This is dependent on the intrinsic or inherent volatility of each component, or, how easy

it is to vaporize the component. A good measure of this parameter is the material's boiling point and vapor pressure. A low boiling point (high vapor pressure) means that it is easy to vaporize (out of the “neat” state, without other interactions), and a high boiling point (low vapor pressure) means that it is more difficult to vaporize at the standard conditions of use (i.e., temperature and pressure).

The ability of a fragrance component to be volatilized may change versus its behavior from the neat state due to its solubility in, or interaction with, a product matrix (Raoult's Law). This phenomenon is often due to its hydrophobicity or hydrophilicity. This variation of solubility character is one that can be quantified and indexed for comparison purposes as the ability of a material to partition between water and octanol. This measurement is represented as the log K_{ow} (Octanol-Water Partition Coefficient) of a material.

Each fragrance component has a *threshold concentration* that must be reached in the air in order for it to be perceived by a working nose. This is called the odor detection threshold. In other words, enough of the vapor has to be present at the nasal sensors to be able to perceive it, but that amount differs dramatically between fragrance materials and people.

a. Volatility / Boiling Point

As we mentioned earlier, the relative volatility of a fragrance material can be indicated by its boiling point. The higher the boiling point, the more energy it takes to vaporize a material, which means it is relatively less volatile. Conversely, the lower the boiling point of a material, the higher the volatility. Broadly speaking, materials that give the grassy green odor characters, citrus notes, and some fruity and lighter floral notes are the most volatile, while the heavier florals, sweet, woody, and musky odor characters are the least volatile. The pyramid chart of Figure 1 can be enhanced to show general fragrance character and volatility relationships in Figure 2.

Figure 2 Volatility vs. Character

b. Hydrophobicity / Hydrophilicity (Octanol-Water Partition Coefficient, log K_{ow})

The solubility of a fragrance material in a homogeneous product base may influence the driving force for the material to vaporize in order to be smelled. Absolute water solubility is not an ideal measurement for how a fragrance material will perform in a product matrix. Of more importance is an understanding of the partitioning of a material between a water phase and an oilier phase (such as octanol). This view provides great insight into how a fragrance material will interact with the base.

A useful, simple description one learns early on is the saying "like dissolves like." This means that hydrophilic materials are soluble in water, and hydrophobic materials are soluble in oil. Dissolving the hydrophilic sugar sucrose in water is easy, while dissolving sucrose in oil is difficult if not impossible. It is probable that some very small amount of sucrose is dissolving in the oil, but the ratio of concentration of sucrose dissolved in the oil to the amount of sucrose dissolved in the water is very small. Conversely, mixing kerosene with gasoline is easy, but mixing kerosene with water does not yield a homogeneous mixture. Again, there may be a very small amount of kerosene dissolved in the water, but the ratio of kerosene dissolved in the oil to the kerosene dissolved in the water will be extremely large.

It is easy to see in Figure 3 what this conceptually would look like. For the mathematically minded chemist the equation is shown in Figure 4, but the important idea is to understand that given a choice of oily phase or water phase, for every 1 unit of log K_{ow}, 1,000 times more material prefers to be in the oily phase as opposed to being in the water phase.

Figure 3 Octanol – Water Partition Coefficient

Figure 4 Octanol – Water Partition Coefficient

Abbreviation: K_{ow}, Octanol-water partition coefficient

The same ideas are at play when fragrance materials are introduced into cosmetic products. Overall, fragrance materials are hydrophobic. Only a select few materials are truly hydrophilic and will dissolve to an appreciable amount in a water phase, but there is a range of solubilities and K_{ow}'s across fragrance materials and therefore to some extent across fragrance characters. Once again we must emphasize that fragrance materials are individual components while fragrance or odor characters are how they smell. A single fragrance material can have several odor characters and can be comprised of several fragrance raw materials. This is very generally described in Figure 5.

Figure 5 Volatility & Log K_{ow} vs. Character

c. Odor Detection Thresholds

Each fragrance material has a concentration at which it just becomes perceivable. From there, increasing the concentration results in increasing the perceived intensity of the material up to some maximum level—after which no further intensity increases are detectable. This is described in Figure 6. The maximum perceivable intensity of each material is different, as is its odor detection threshold. It is more difficult to broadly assign fragrance characters to high threshold materials (need a lot to be able to smell them) and lower threshold materials (very low concentrations are able to be smelled). However, it is not surprising that characters related to ripe fruits and other foods have low thresholds to humans so that we are attracted to them. Also, characters related to fecal matter and decay also have very low thresholds, and result in humans being repelled by them. Characters like flowers, woods, and other "survival-neutral" types have higher detection thresholds. This is represented in Figure 7.

Figure 6 Fragrance Ingredient Perception

Figure 7 Volatility & K_{ow} & Threshold vs. Character

When Perfumers design a fragrance, these thresholds and intensities are optimally incorporated into a formula that smells "balanced" such that no single material is immediately identifiable. Figure 8 The whole mix smells harmonious, and the entire mixture performs across many evaluation or product usage points such as out of the bottle. Figure 9 As products are used, the odor profile of the fragrance changes due to the changes in concentration of the fragrance and the product. For example, when using a shampoo, the fragrance is at its highest dosage while it is in the bottle and applied to the hands. Then, when water is added and the product (and fragrance) is diluted, concentrations of each

fragrance material will eventually fall below their detection threshold and disappear from the odor profile. This shift is seen in Figure 10.

Figure 8 Fragrance Ingredient Mixtures

Figure 9 Fragrance Perception – Concentration

Figure 10 Fragrance Perception – Concentration

There are a few other phenomena that are sometimes mentioned with respect to detection threshold. “Anosmia” occurs when a specific person is unable to smell a specific material no matter the concentration. It has been well documented that many people are genetically unable to smell a certain type of musk, sandalwood, rotten fruit, or other very specific types of odorants. Total anosmia to all odorants is rare, but does occur; however, it is more likely to occur from injury, medications, or other trauma than genetic factors.

“Saturation” occurs when one has smelled a strong material at a high concentration that temporarily blocks any receptors from other odors, presumably due to saturation and overload of the receptor. This phenomenon is reversible and after a period of fresh air or overnight exposure the inability to smell will reverse itself. This may occur when smelling material with very low detection thresholds.

“Adaptation” occurs when an odor is smelled so often that the brain doesn't recognize it any longer. For example, when entering the monkey house at the zoo, the stench is often unbearable, but after a few minutes one doesn't really notice the odor. Upon exit and reentry, the process repeats itself—which could be adaptation and saturation presenting at the same time.

It is also useful to mention that some odorants show themselves not only by smell but by triggering a trigeminal nerve response. For example, ammonia has a characteristic odor but this odor may not be able to be covered as it also has a significant trigeminal response, which is an entirely separate neurological pathway from fragrance detection. It is for this reason that the smell of ammonia is extremely difficult or impossible to neutralize by fragrance alone.

1.2.6 EVALUATION OF FRAGRANCES

Fragrances used in personal care products are judged by the consumer at several stages in a product's use cycle. These use cycles are quite different among products and can have a significant impact on how Perfumers will create a fragrance for a specific product. For this reason it is important to explain to the fragrance house the intended nature of the product as well as its use-cycle in order to facilitate selection of the fragrance(s) that will be recommended. Each major event in a product-use profile has the possibility of being an evaluation point for the consumer, and should also be a point of evaluation for the chemist. Usually one evaluation point is more important than all the others, and it is highly useful to identify that evaluation point and ensure that the fragrance and product perform very well at that key point.

During an evaluation, the consumer (or the Evaluator) will consider the fragrance's character as applied to the product base, and the fragrance intensity. At times, the fragrance can be perfect with respect to character, but one must choose an intensity that is consistent with the product's use to make a perfect product. For example, the fragrance intensity of a high-end facial crème is usually much less than the fragrance intensity of a mass-market body crème. An Evaluator will be well aware of this difference and help recommend a level that is typical and appropriate for a product, while a Perfumer may be more likely to want to push the creative envelope.

a. Product-Use Cycle

The product-use cycle may start at the point of purchase. Many packages can be opened and the consumer can smell the fragrance of the product. On this basis alone, consumers can, may, and do make a decision as to whether the product will be purchased. It is also of great importance that the container for the product (and the fragrance) as well as the final packaging can actually be opened. Fragrance packaging design has been covered elsewhere in this book.

The fragrance house will focus strongly on this evaluation point. Normally in the fragrance house, all the potential submissions of the fragranced product will be evaluated against a control or benchmark if applicable. Products are usually compared to each other in 1–2 ounce wide-mouthed bottles with approximately 50% headspace to standardize the comparison conditions. From that selection, the fragrance house's Evaluator will choose a few to submit to the cosmetic chemist and marketing expert. Normally at least two to three times the amount of

final submissions will be compared internally and the best of these will be submitted. The remainder are put into the fragrance house's library for future use as mentioned previously in this chapter.

For packaging that cannot be opened, the consumer product-use cycle starts at the point where the consumer dispenses the product. This generally involves the dispensing and manipulation of a certain amount of product on the hands, and the evaluation point is then on the hands themselves. This is a difficult point to standardize and is considered by the fragrance house in the overall evaluation process—but not as a standalone evaluation point like many of the key evaluation points.

For rinse-off product categories, generally the next step in the product-use cycle is the addition of water to the product/fragrance in the hands or the application of the product to wet skin or hair. At this stage the “bloom” of the fragrance is very important, as usually the consumer is looking for a *burst* of pleasant fragrance to reinforce the product's claims. This is often the key evaluation point for the rinse-off type categories.

Then the product is rinsed out, leaving a certain amount of fragrance on the wet skin or hair. This is an evaluation point as well, but generally is not considered a key point for cosmetic products as opposed to laundry detergents or fabric softeners, where it may be the significant in-use evaluation point.

Finally, the skin or hair is dried, and there are further opportunities for consumers to evaluate the product's smell. Again this is normally not a key point of evaluation for consumers unless there are some type claims at this step, but the fragrance of the product and what is left after the whole use process should be pleasant.

For **lotion-type products or leave-on products** the point of evaluation after application to the hands is the application step where the consumer will rub or apply the product to the hair or skin in a manner consistent with the product category. The product's fragrance character and intensity at this step is very important to help reinforce the attributes of the product, and this can be very much a key evaluation point for products like facial lotion or hair gel.

For **leave-on products**, the evaluation stage continues for the remainder of the intended product effectiveness time frame with varying importance across product categories. For example, in a body lotion, the consumer may wish to be reassured the moisturizing effect has continued for several hours after application, making this perhaps a key evaluation point. However, for a hair gel,

the fragrance intensity and character after several hours of application is fairly irrelevant as long as it is not unpleasant and the product is still holding the hair firmly. All this is in contrast to a fine fragrance where every single moment from the moment of application to the moment in which the fragrance is washed away could be considered a key evaluation point.

b. Fragrance Complexity

Perfumers must create fragrances to be pleasant and appropriate at each of the key evaluation points in the use process. Multiple evaluation points usually indicate the fragrance will need to be more complex and take more time to create and evaluate within the fragrance house. As such, the fragrance created for this type of situation is usually more sophisticated and will be on the higher end of a price point to make a fragrance that will really “wow” a consumer. Certainly less expensive fragrances can be acceptable, but will compromise on certain evaluation points. It may be up to the fragrance decision-maker to determine if the compromises are within the scope of the project and its intended market. Any unusual information about the relative importance of evaluation points should be communicated to the fragrance house; otherwise, the fragrance house will use what seems to be the most appropriate for the product type.

1.2.7 LIMITATIONS OF FRAGRANCES

Fragrances are used to impart a pleasant odor to a product and cover the usual malodor of the product base, in addition to helping reinforce the product's performance benefits. Unfortunately there are some odors that occur in a product base that are unable to be completely masked by fragrance. Highly volatile (gaseous) and strong odors such as ammonia or sulfur dioxide from bisulfite-containing products can be mitigated to some extent, but because fragrances are made from materials with lower vapor pressures than these gases, there is very little hope that a fragrance will vaporize and reach the nose more quickly than these types of odors. Fortunately, concentrations of bisulfites in products tend to be low enough to allow fragrances to have a positive effect on this odor, but ammonia in products such as hair color is at a concentration such that only a little effect may be noticed.

1.2.8 COST STRUCTURE OF FRAGRANCES

Fragrances are constructed of the odiferous natural and synthetic fragrance raw materials described above and, usually, approximately 5 to 20% an odorless carrier that is technically necessary for the fragrance's physical stability, or is introduced as a processing aid for one or more raw materials. The major cost associated with the fragrance is in the actual odiferous fragrance materials. The carrier materials are normally relatively less expensive, but they still add a certain cost to the fragrance formula as demonstrated below.

Fragrances often contribute a proportionally larger cost to a final product than many of the other materials, or are much more expensive per pound or kilo than many of the other materials in the product. However, it is not a good idea to ask the fragrance house for a diluted version of a fragrance just to reduce the purchase price per pound of fragrance. It is best to calculate the contribution of the fragrance to the final product and use that as a guide to whether the fragrance is affordable or not for that product.

a. Carriers

Fragrance houses often ask which type of product the fragrance will be used for. This information is important for the Perfumers to decide which carrier will be used in the fragrance. Carriers such as dipropylene glycol have little solubility in products such as bath oils or some silicones, while very hydrophobic carriers such as isopropyl myristate that may work in oils and silicones may not be appropriate for a sulfate-free shampoo. Using past experience, the fragrance house will match an appropriate carrier with the product type. If an unfragranced product base can be provided to the fragrance house, they will often make tests to ensure that the fragrance is appropriate for the product and will, generally, be able to provide a recommended use range for the fragrance.

b. Concentration-Cost Considerations for Fragrances

Buying a fragrance that is as concentrated as much as possible is the most cost-effective approach to using a fragrance. An easy way to see the advantage of using a concentrated fragrance is to consider a fragrance that costs 40/kg. If the fragrance is formulated into a product at 0.5%, the cost contribution of the fragrance is $0.20 per kilo of finished product. If the fragrance house is told to reduce the purchase price of the fragrance to $20/kg, and it is just diluted with additional carrier costing $7.50/kg, then the concentrated “smelling” part of the fragrance is now not 50% of the formula. However, due to the cost of the carrier, it will be only approximately 38% of the diluted formula. Figure 11

Figure 11 Dilution Reduces Fragrance Activity

To provide an equivalent olfactive effect (such as achieving the same intensity) as the original fragrance, more of the diluted fragrance would have to be used, so in this example the dosage needed of the dilute fragrance would be 1.3% in the final product (versus the 0.5% of the original concentrated fragrance). The 1.3% of fragrance used in the same product contributes $0.26/kg to the finished product. It is $0.06/kg more expensive to use more of a dilute fragrance in a finished product than it would be to use a lower dosage of a more concentrated fragrance, even though the purchase price of that fragrance as a single ingredient is higher. Aside from cost consideration, the additional carrier may affect the physical properties of the finished product or cause other issues. The bottom line is that it is preferable, when possible, to use as concentrated a fragrance as is reasonable.

1.2.9 TROUBLESHOOTING FRAGRANCES

There are times when fragrances can cause a product base to have a shift in color or odor, or cause separation. Color or odor stability issues may be particularly evident in a rapid-aging testing technique or exposure of the fragrance to UV or fluorescent lighting conditions. Phase stability (separation) issues may present themselves as part of a freeze-thaw process—where the product will turn into distinct layers; or if there are pearlizers used in a product, one may see a separation of the pearlizers upon heating that is not reversed upon cooling. Before approaching a fragrance house to solve an issue, it is imperative to ensure that the unfragranced base under the identical conditions did not have the same

issues as was seen in a fragranced sample. If the unfragranced base turned the same color or phase split under the same conditions, then it is probably not the fragrance alone that is causing the issue.

Once it is ascertained that the fragrance is causing or exacerbating such issues, document the condition(s) in which the issue(s) was noted, the dosage of the fragrance, the packaging in which the condition was noticed, how long it took to occur, and any other details that will help the fragrance house reproduce the problem. Normally, the fragrance house will try to reproduce the change in the actual product base, and have a Perfumer rework the fragrance formula to help alleviate the issue. Much of the time the odor profile of the fragrance will be intact, but there are times that a shift must occur. It is best to provide the fragrance house with an unfragranced base to test variations of the fragrance and to allow enough time for a few cycles of variations to occur.

a. Color Changes

Shifts in color of a finished product are sometimes caused by fragrances. A very sweet, gourmand fragrance containing a lot of vanilla or spun-sugar notes will often turn a product yellowish or sometimes light pink. Many times there is not a good way to keep the same fragrance character and solve the issue of color change. Addition of a chelating agent and ensuring the product is slightly acidic, if possible, can help.

Very grapey, fruity, or thick jasmine or tuberose-type fragrances may turn a product pink. Often the only solution in this case is to reduce the amount of that note in the fragrance, which may change the character of the fragrance.

b. Physical Product Stability

If a finished product is not phase-stable when the fragrance is incorporated, it may be that a change in carrier will solve the issue. A change in carrier or solvent will not affect the character of the fragrance to any appreciable extent. For example, in a bath oil the carrier dipropylene glycol will form a second phase in the product, whereas isopropyl myristate will yield a homogeneous product, due to the hydrophobicity of the carriers versus the product solvent. A very good carrier for all product types is diethyl phthalate, but many consumer-product companies no longer allow the use of this carrier. At this time, benzyl benzoate, isopropyl myristate, dipropylene glycol, triethyl citrate, and Polysorbate 20 are the most common carriers.

c. Odor

For odor changes in a stability test, typically either the fragrance just fades away without having any negative odors, or the fragrance "turns" into something that does not have a pleasant odor. Again, especially in the latter case, it is imperative to determine that the fragrance is the cause of the negative odor, and that this odor is not present in an unfragranced base subjected to the same conditions. If the fragrance is the issue, it may be reacting with the product base or active materials in the base and probably will have to be reformulated or exchanged for a different fragrance without the same issues. Overall, one must consider that the fragrance and the product base are basically in a dance with each other. When negative issues result from their combination, one must not jump too fast to the conclusion that the fragrance is the cause.

1.2.10 FRAGRANCE TYPES DEFINED

There are many different categories of "fragrance," and knowing which one to ask for is important to make a successful and cost-effective product.

a. Traditional or Standard Fragrances

Traditional or standard fragrances are mixtures of natural and synthetic materials in some concentration and a carrier. If desired, the natural materials can be "called out" for inclusion on the label, but certainly the rest of the fragrance is listed on the ingredient label as "fragrance." Most traditional fragrances contain from 5 to 20 percent carrier, which may act as a fluidizer/solvent in the event that the raw materials have a low melting point. Use of a fluidizer/solvent will prevent undesirable crystallization. This approach is useful for ease in production of the fragrance, or may be included by the Perfumer to ensure that any crystalline materials stay in solution when shipping during the colder months.

Traditional fragrances are the most common in the marketplace and they can be made in nearly every odor character imaginable, and for nearly any price point. They are also very versatile, and can usually be modified to work well in almost any type of product. If at all possible, this is the best alternative for a fragrance and one that will most likely be optimal regarding its relative cost-stability, versatility, adaptability, and robustness.

If a fragrance house is just asked for a fragrance without any other information, the supplied fragrance will be a traditional fragrance.

b. EU Allergen Label Free or Allergen Free

Based on a consensus of the Scientific Committee on Cosmetic Products and Non-Food Products (SCCNFPP), it has been reported that certain fragrances contain up to 26 dermal allergens as defined in http://ec.europa.eu/health/scientific_committees/consumer_safety/docs/sccs_o_07

As a result, for products sold in Europe, the European Union (EU) has mandated that if any of the 26 purportedly regulated dermal allergens are present above certain levels in a finished product, they will need to be listed as an ingredient on the product label in the Ingredients section per the European equivalent of the PCPC.

If a product will be marketed in Europe, these materials *must* be listed on the ingredient label. The fragrance house should be notified up front that a fragrance needs to be "EU Allergen Label Free" if none of the 26 allergens appear on the product label.

The ramification of having an allergen-label-free fragrance is that the Perfumer's palette becomes limited, as no natural essential oils can be used in the creation of a fragrance containing them. As one might imagine, this regulation has had significant effects on many previously formulated, well-known fragrances.

c. Water-Soluble Fragrances

As described above, the vast majority of fragrance materials have no appreciable intrinsic water solubility, which means that fragrance oils, overall, are not water soluble. However, some finished products, especially those without much surfactant or much of an oil phase, require the use of "water-soluble fragrances" in order to yield a transparent product or one that will not separate into distinct phases. An example of this type of product is a water-based hair gel. The designation "Water-Soluble Fragrance" (often abbreviated by the fragrance house as WS appended onto the fragrance name) is in fact a bit of a misnomer. If asked for this type, a fragrance house will supply what is in essence a "presolubilized" fragrance. This is actually a concentrated fragrance oil highly diluted in an affordable surfactant such as one of the Polysorbates. The purpose of the surfactant as a diluent is to provide enough surface-active compatibilizing agent to solubilize the fragrance concentrate—irrespective of the amount of that material in the final product. The amount of surfactant-compatibilizing agent in the fragrance supplied can be appreciable, and is typically 70–80% of the blend,

since the house will likely overdilute to ensure enough surfactant is present to solubilize the fragrance oil. This means that only 20–30% of a “WS” fragrance is actually providing an olfactive quality to the product, and the rest is odorless surfactant of the fragrance house's choice. If the means are available, it may be much more cost effective to buy a concentrated fragrance from a fragrance house and presolubilize it with an appropriate surfactant for the product at only the required level. This amount could be less than the typical ~70% level supplied by the fragrance houses.

A good starting point to accomplish making a presolubilized fragrance is to mix two to three parts surfactant of choice to one part fragrance oil and check it in the final product at the desired dosage (taking into account the dilution). If the final product is not transparent enough, or if the final product forms two phases, then more surfactant is needed. For some types of fragrances, up to four–five parts of surfactant to one part fragrance oil may be necessary to yield a clear product. It is also appropriate to ask the fragrance house to use dipropylene glycol as a carrier if possible since it has the most water solubility of all the commonly used carriers and will result in requiring less surfactant to solubilize the fragrance. It is also important to note that all-natural fragrances are usually the most hydrophobic types and these will need the highest levels of surfactant-compatibilizers to solubilize them if in fact it is possible.

d. Water-Dispersible Fragrances

A “water-dispersible” fragrance (often abbreviated as WD appended onto the fragrance name) is one in which only enough of the surfactant is added (as described above) to form a semi-stable dispersion of the fragrance oil in water. Typically the “WD” fragrance is 50% surfactant and 50% fragrance oil, but can be as low as 30% surfactant and 70% fragrance. This dispersion will likely be hazy, but will not separate into two phases for some period of time so that it can be used in a production or application process. This type of dispersion is normally used in applying fragrances to products that are fragranced at a low level and require some kind of diluent for the ease of application and for accuracy in measurement of the fragrance dosage. For example, if a facial wipe is to be fragranced at 0.010%, the fragrance may need to be diluted in water so that 0.100% of the resulting mixture is used, and the diluting water is added into the water already in product formulation.

e. INCI Blends

INCI Blends are fragrance mixtures in which each individual material has an INCI name as listed by the Personal Care Products Council (PCPC, formerly the CTFA, website listed above), so that the label of a product, as provided to the consumer, does not need to include the word “fragrance,” and instead need only list the blend ingredients separately. The fragrance house should be asked to provide a listing of the ingredients used in these blends once they are approved. Normally in order to do so there is a confidentiality agreement or equivalent in place. It is absolutely necessary to ask the fragrance house for an INCI blend up front, as they are not the norm, and generally require special creation. These INCI blends are typically extremely simple compared to the average fragrance and have very simplistic and singular odor characters since there are so few materials used in their construction.

1. Natural INCI Blends

Not all natural materials or essential oils have an INCI name, so it is necessary to determine the exact purpose of asking for a natural fragrance. If the product needs to be “All Natural” *and* will list the fragrance ingredients on the ingredient label *and* must exclude the word “fragrance,” then asking a fragrance house for an “All Natural INCI Blend” would be appropriate. If the only requirement is a “Natural Fragrance” and the word “Fragrance” or “Natural Fragrance” can appear on the product ingredient label, it would be more appropriate to ask just for a “Natural Fragrance.”

A Natural INCI Blend is an extremely restrictive requirement, and the resulting blends are fairly limited in scope. Natural materials are generally the most expensive. If pricing restrictions are imposed on the fragrance house, typical cost-reducing carriers would be the highly hydrophobic hydrogenated soybean oil or medium-chain vegetable triglycerides or other inexpensive stable oils. Again, it may be best to have as concentrated a blend as can be afforded. The advantage of this is that one can use less of it as opposed to getting a less expensive diluted natural INCI blend. Such blends can cause phase stability or viscosity issues in the product or necessitate the use of more surfactant to incorporate it into the product. It should also be noted that natural fragrances, whether or not they are INCI blends, are subject to wild fluctuations in cost due to seasonal variations, crop yields, and availability of materials, as described previously.

2. Allergen-Label-Free INCI Blend

An “Allergen-Label-Free” INCI Blend is the most restrictive requirement for a

fragrance oil. In this case, no natural essential oils, absolutes, or other complex natural (i.e., must be from an essential oil, or an "absolute") products can be used, but only chemicals that have an INCI name *and* are extracted from essential oils or have another natural source.

Nearly all natural essential oils or absolutes contain one of the currently recognized 26 EU dermal allergens at levels that would preclude their use completely. In the case of asking for an "Allergen-Label-Free" INCI Blend, one would need to list on the ingredient label the actual chemical names of the blend materials. This approach may defeat the overall purpose of having an INCI blend, since the long, unfamiliar names of the "chemicals" may seem onerous to the final consumer and will not differ from the negative impact and consumer perception of their synthetic counterparts. Most of these blends by definition must be fruity in character. They will have little to no base notes, a limited number of middle notes, and therefore will mostly be composed of volatile top notes. Further, they will not be appropriate for the most part to mask any base odors from the product. Such materials would be most appropriate for very clean bases that need a fleeting hint of fragrance.

3. Traditional INCI Blend

A traditional INCI blend will contain only fragrance materials that have INCI names as per the PCPC (Personal Care Products Council). They will likely contain some natural essentials oils and some artificial chemicals. These blends can be quite beautiful fragrance-wise but are typically somewhat limited in fragrance character. They do tend to be more affordable than natural INCI blends (and in many cases will have similar INCI names). It should be communicated to the fragrance house how many materials (or letters) can be supported on the ingredient label. Generally, the more ingredients, the more acceptable the fragrance character or odor.

4. "Unscented" INCI Blend

An "unscented" INCI blend is a very simple blend of neutral-smelling materials with INCI names that help mitigate the base odor of a product but do not add any recognizable fragrance quality to it. These blends typically contain two to three materials. These types of blends are useful for products like eye cream or facial cream or a type of product that has some odors from the actives but does not need a characteristic fragrance odor. Note that the base odor from the product will not be totally covered but will likely be more palatable to the final consumer.

f. Natural Fragrances

If the only labeling requirement is a "Natural Fragrance" and the word "Fragrance" or "Natural Fragrance" can appear on the product ingredient label, it would be appropriate to ask the fragrance house for a "Natural Fragrance." If the product needs to be "all natural" *and* will list the fragrance ingredients on the ingredient label *and* must exclude the word "fragrance," then asking a fragrance house for an "All Natural INCI Blend" would be appropriate (see above).

Natural fragrance materials can include essential oils, absolutes, concretes, and natural fractions of essential oils (which may be a single material, normally called an "isolate"). Natural materials may also use fermentation reactions and other ways to produce materials that are not synthetic.

Natural fragrances can vary dramatically in price from month to month and year to year, and shortages or quality problems in the starting essential oils can occur.

1. Traditional Natural Blends

Traditional natural blends use a combination of essential oils, absolutes, concretes, isolates, and fermentation products. The result can be a fragrance (although fairly limited in odor character) that is pleasant and somewhat complex and can be referred to on the label as a "natural fragrance." If asked for a "natural fragrance," most fragrance houses will send this type of traditional natural blend.

Natural fragrances are generally three to ten times more expensive than traditional fragrances and the odor characters are somewhat limited. Knockoffs of fine fragrances are impossible, but quite pleasant floral mélanges with some woody base notes and fruity top notes would be possible.

2. Essential Oil Natural Blends

Essential Oil Blends are a very limited version of a natural fragrance. These blends incorporate *only* the entire essential oils obtained from a plant or citrus fruit peels. They do not contain absolutes, concretes, or single material isolates. Such materials are very limited in character because they contain only citrus, leafy herbal, lavender, some woody, and a very few floral characters and their resulting blends. It is necessary to specify to a fragrance house that an "essential oil blend" is needed, and the fragrance house may have questions about the allowed types of materials.

Essential oil blends are the most expensive as well as the most limited in

character, and their pricing over the season varies wildly as many essential oils increase dramatically in price when not in season.

g. GRAS Fragrances (Generally Recognized as Safe)

GRAS fragrances are a niche specialty fragrance type necessary for lip balms or other products that may enter the mouth or penetrate the lips, or are for children's toys. GRAS fragrances are those in which each fragrance material has a flavor FEMA-GRAS number and/or is recognized as a flavor material. These fragrances also must meet all of skin contact requirements for the product category in which they are used. GRAS fragrances, nearly by definition, tend to be fruity or food-related in character. They tend not to be long lasting and are usually quite simplistic in character.

CONCLUSION

Fragrance development is very important to the success of a consumer product. Not only will the character and intensity of the fragrance reinforce the product's benefits, but they will also add appeal to the consumer. Understanding the basic technical requirements of a fragrance and knowing how to interact with a Fragrance house will greatly enhance the success of the cosmetic chemist and ultimately the product.

PART 1.3

FRAGRANCE PACKAGING DESIGN:

A Multi-Sensory Experience from Concept to Consumer

Renee Bukowski
Senior Product Development Manager

Tru Fragrance and Beauty
1250 Broadway, Suite 1901
New York, NY 10001

ABSTRACT

The benefits of cosmetics and personal care products are both tactile and functional, providing a temporary benefit by enhancing the appearance of the face, body, or hair.

By contrast, fragrance transforms the moment, awakens the senses, creates indelible memories, and captivates the people in a room. The consumer's experience of fragrance is subjective, abstract, conceptual, and emotional. The combined expertise of the marketer, perfumer, and designer is dedicated to focusing on the development of a product that communicates an emotional link and provides a cohesive, holistic sensorial experience to the consumer. Sensory cues are used throughout the packaging to communicate the olfactive character of the product as well as the emotional story; and these cues are the foundation of a successful fragrance. In this chapter, experts have been interviewed across all components of the development process, and a review of research has been compiled in order to expand the knowledge base of product developers and educate further about the stages of a cohesive fine-fragrance development process.

With over 1,000 fine fragrances launched globally in 2011, what is the best way for fragrance brands to stand out in the eye of the consumer and generate revenue for the brand? Expectations are set for the consumer through sensory cues such as the bottle, packaging, color story, and scent. If these elements are not aligned, consumers can experience sensory dissonance. The five senses are core to human experience and are essential to our perception of the world. In today's beauty industry, marketers, perfumers, and designers need to work in tandem in order to meet tight timelines and anniversary sales and to be

competitive in the marketplace. But is the final product always optimized? Were there connectivity points between the team to maintain synergy for the final product? Does it communicate the concept to the consumer?

Primary Question for Product and Brand Development:

What can companies do to integrate their internal process in order to produce a unified product the consumer will positively respond to, accept, and ultimately purchase?

1.3.1 INTEGRATED PROCESS: THE BRIEF

Led by Brand Development or Marketing, a document called the “brief” outlines the objective and strategy for the finished product. The brief is shared with Product Development to initiate the project. After the initial review, additional briefs can be developed, narrowing the focus and outlining evolving details of the project. The initial brief puts the project in action, and detailed briefs such as the fragrance brief and creative brief are viewed on a micro level for the designated department. Product Development also creates a project timeline and a component pricing analysis, which outlines the budget for the product.

Initial Brief or Project Profile

- Brand identity
- Target consumer (demographic and psychographic)
- Quantitative and qualitative research results, if applicable
- Product positioning and white-space opportunity
- Competitive analysis
- Pricing and cost targets
- Quantity
- Distribution
- Target ship date

Fragrance Brief

- Brand overview
- Target consumer with focus on psychographic
- Concept: Olfactive story
  - Mood board
  - Color direction
  - Product personality
- Olfactive category direction: Primary and Secondary
  - Primary: citrus, floral, fougere, woody, chypre, oriental
  - Secondary: citrus, marine, aldehydic, aromatic, green, floral, spicy, fruity, musky, gourmand, leather/animalic
- Oil cost target / Fragrance blend percentage
- Olfactive market inspiration or benchmarks
- Fragrance color
- Distribution (in order to understand compliancy restrictions)
- Regulatory and stability requirements
- Timeline for deliverables

Creative Brief

- Brand overview
- Target consumer
- Product positioning
- Concept
- Component direction
- Color direction
- Olfactive direction
- Existing brand assets (logos, fonts, imagery, color)
- Budget
- Timeline for deliverables

While all the departments are working simultaneously, it is important to have connectivity points throughout the process in order to confirm alignment and clear direction towards achieving the ultimate goal.

Throughout the development process of a product, it is essential to think about the left-brain and right-brain functions you want the consumer to experience with the product. One must ask, "How will the consumer react to the product emotionally, creatively? How will the product function? What will the consumer experience through sensory cues? How will the concept or story be successfully translated to the consumer?" In developing sensory cues it is important to consider how each cue will translate the scent to deliver the concept to the consumer.

1.3.2 SMELL THROUGH HEARING: CONSUMER TESTING

Curate and guide the development process based on consumer findings.

Gail Vance Civille, President of Sensory Spectrum Inc., has pioneered advanced sensory evaluation approaches for industry, academia, and government. She shares that ideas are coming directly from the consumer. Preliminary concept work should involve consumers in order to understand what types of messages are being communicated through product design. A hybrid approach using qualitative and quantitative testing can provide insights as to what the consumer wants and needs, and how the concept and marketing messages are being perceived.

Qualitative Testing

- Field Testing
- Shop-alongs
- In-home visits
- Diaries
- Focus groups
- Interviews
- In-store intercepts

Quantitative Testing

- Surveys
  - Multiple choice
  - Numeric

Mark Knitowski, the “Nose” behind all the Victoria’s Secret scents, does not consider himself the “expert” in developing fragrances for his consumers. Rather, he considers himself the “curator of fragrance” and the “protector of the consumer information.”

Further, Knitowski believes the consumer should not be “sold” a fragrance, but they should embrace a journey with a scent and connect to a well-told story. “The right fragrance should be part of an emotional journey, reflecting how a woman or man feels about themselves and how they want to project the image of themselves to the world.”

By using over 1,000 of the Victoria’s Secret stores as direct access to the consumer, Knitowski involves them in the development process. He spends time in the stores engaging consumers with general day-to-day conversations through in-store intercepts. He may also test two fragrances that he’s been developing to gain feedback and perspective. He first has the consumer smell on skin and then on a blotter, the scent strip used to test fragrances. The consumer then smells the fragrance completely blind without any sensory cues. From their response, Knitowski is looking to understand whether they would purchase the scent, and what adjectives they use to describe it. Through the qualitative learning extracted from his consumer studies, Knitowski further evolves the scents based on the comments from the consumer. Each component, including the fragrance, carton, bottle, and name, are tested independently and then together. If one of these elements does not align to create a holistic finished product, then the consumer will not align with the intended concept.

As an example, Victoria’s Secret product “Bombshell” was the perfect blend of fragrance, bottle, and packaging—but it did not start out this way. The fragrance tested so positively that there were no dislikes out of 150 paneled, yet when the scent launched under the name “Signature” in a rounded bottle, the results were less than successful. After analyzing the less-than-favorable response, the team knew the fragrance was not the problem. This observation became a turning point for creating a product success and is an excellent example of the role of the development team realigning and modifying the product based on consumer results.

The next test that was initiated included the same fragrance with a more faceted bottle and a name that aligned with a recent bra launch, Bombshell. Led by Marketing and Design together, these adjustments built the foundation for a successful fragrance that ultimately won a Fifi award for Best Packaging in the Specialty Market and a Consumer Choice Award; it was also voted Fragrance of the Year in 2011. The positioning within the Bombshell lingerie master brand enhanced the fragrance story by giving it depth and an emotional connection. The adjustments to the bottle further enhanced the cohesiveness of the product because it aligned with the overall product positioning in a way that resonated with consumers.

Marketing and Product Development need to consider both qualitative and quantitative testing. Throughout the testing process it is important for the developers to listen closely to what the consumers are saying, while also maintaining the integrity of the concept. By closely "smelling" the direction through listening to the consumer and curating the learning, a successful fragrance, Bombshell, made history.

1.3.3 SMELL THROUGH SEEING: FRAGRANCE NEEDS COLOR

"Used wisely, color is vitally important and is an instant attention grabber that succinctly gets the message across." (Pantone Color Institute)

Color is perhaps the strongest cue in aligning the consumer's expectations with the desired fragrance experience. Through the fragrance, carton, bottle, and

color, olfactive direction can be communicated, as well as the brand's emotional positioning. The relationship between color, scent, and emotion can impact a consumer's emotions. What does yellow smell like? What branding cues does red communicate? It is imperative to have color direction in the initial product profile or brief because disconnect in the color with the other elements of the fragrance can confuse the consumer.

Here are some examples of the message a color in a fragrance can communicate:

Blue—calm, watery, ozonic

Green—revitalizing, fresh, nature, eco-conscious

Red—sexy, powerful, confident, energizing

Purple—luxury, mystery, exotic, royalty

lesight 2012)

Marketers can leverage color to communicate newness within a portfolio and to distinguish flankers, or fragrance variations, from the original, while also aligning with trends. Fashion color trends relate closely to the beauty industry and change based on the season and geographic location. Forecasting services are a key reference in aligning with trendsetting color palettes, Marc Jacobs's Daisy, a fragrance product, is an example of how color has extended the brand lifecycle by communicating a prestige eau de parfum version through the use of richer colors such as black and gold, silver and gold, and red and black. Also, seasonal color stories stimulated demand and further differentiated a limited-edition bottle. Once consumers see the color and packaging of a fragrance, they already form an opinion and their expectations are set.

Coty's Senior Vice President, Catherine Walsh, is known as the "scent whisperer." She is the generating force behind brands and celebrities such as Jennifer Lopez, Calvin Klein, Marc Jacobs, and Sarah Jessica Parker. Walsh has stressed that it is critical for all teams involved in the development of a fragrance to be aligned all the way through the process. Marc Jacobs's fragrance Dot was launched in 2012, but the initial concept and color direction the Coty team was working towards was very different than the polka dot red-and-black fragrance that hit the market. Marc Jacobs changed the direction because he was inspired by a stronger story that was more meaningful to him and tied to his fashion line. Polka dots have been a recurring theme for the designer, and were a major focus for his Fall 2012 ready-to-wear line. "One design that I always go back to in some way is the dot. I felt like this was something I'd never get tired of, and I'll always find a new way to interpret," Marc Jacobs said. He liked the idea of a hybrid butterfly/lady bug, which communicated the Dot story of free spirit, femininity, playfulness, and luck (Naughton, 2012).

With this significant direction change, Coty communicated all the details of the new concept, the polka dot design and the red-and-black color story through all departments so that Marc Jacobs's strong vision and story could be communicated to the consumer.

As a trend leader in the fragrance industry, Coty utilizes consumer testing and research to better educate the marketers to learn how to lead consumers to the next trend. Trend-leading brands need to maintain the integrity of the brand identity and the character of the concept to offer consumers a product they did not know they wanted until they saw it—and of course smelled it.

1.3.4 SMELL THROUGH TOUCHING: HOW WILL THE CONSUMER FEEL?

The consumer will first see the packaging and the bottle. If the packaging and bottle appeal to the consumer, they will then pick it up: this is the first goal of the marketer. Bottle engineers need to think of the following when developing the bottle: how do you want the consumer to feel emotionally when they pick up the bottle? Does the bottle have soft edges and a lightweight feel or is it rigid and weighted? In one example, Tru Fragrance and Beauty worked with a bottle engineer to create a fragrance bottle for a men's apparel sport line. The Product Development and Creative teams needed to think about this product from an active man's perspective. The bottle was built so the male consumer could grab the bottle and go. Ergonomically tapering through the bottle gives it an aspect of comfort in the man's hand and the built-on spray-through cap allows for easy spraying any time without leaking. The weight was also considered, since the product was designed to be thrown in a gym bag and be a portable fragrance. While the glass is lightweight, the black base and overcap are weighted to give it a feeling of a dumbbell. The development team consciously thought about how the man would use the fragrance and how it would feel in his hand.

1.3.5 SMELL THROUGH SMELLING: TELL A STORY, PAINT A PICTURE

Fragrance is an art. Marketers provide a fragrance brief to the fragrance house. The brief includes as much information as possible about the brand DNA, packaging direction, color direction, target consumer, and store environment. Most importantly, the brief should contain a sensory story and paint a picture in the mind's eye of the consumer. The perfumer is no different than a poet or composer, so a marketer needs to convey the story of the product visually and verbally to stimulate the perfumer. To be successful, consideration should be given to an overall view of the use of the product anticipated. The marketer must set the stage in a variety of ways. Set an environment; describe the dream. What is the temperature? Is it hot like the sun or hot like a fire? How does it feel on skin? Is it humid or comforting? What is the mood of the environment? Is there music on the beach during the day in a tropical place with laughter and dancing, or are you warm and cozy next to a fire in a cabin in the mountains?

A fragrance evaluator, whose purpose is to work closely with the perfumers and optimize their ideas, reviews the brief. The evaluators represent the marketer, and the objective is to really put themselves not only in the shoes of the marketer but really to encompass their identity. They need to take on the role of the marketer, to learn the marketer's tastes and how they think, and to fully

understand them in order to achieve the best fragrance submissions.

CONCLUSION

Falling in love with fragrance. The perfumer begins to blend the "story" based on the brief and visual mood board and works closely with the evaluator throughout the process. Once the fragrance is chosen, it is the marketer's responsibility to take the "story" that is bottled up and make sure that the story is released to the consumer through all the sensory cues so the consumer can experience the story and fall in love with the fragrance.

By means of the use of sensory cues and integrating the development process the concept is successfully shared with the consumer. The story becomes the consumer's dream and each time the fragrance is used, the mood is impacted by how they desire to feel. Sophisticated, romantic, casual, masculine, sexual, playful…the consumer's dream comes true—and this is why people love fragrance.

Glossary

**** A note from Meyer R. Rosen***

Before we get started on perhaps one of the most complex chapters in this book, we call attention to the fact that many readers will not be familiar with numerous terms used in the text. To this end, a glossary has been created at the end of the chapter. To facilitate understanding, note that in the text all "big" words, unfamiliar to many, have been bolded, and a concise definition is presented in the glossary.

As Editor-in-Chief of this book—I take it as my duty to urge you, the reader (no disrespect intended) to grow in the 50-year-old tradition of Harry's Cosmeticology. The contents of this chapter are deemed so important that,

taking editorial prerogative, it has been put in the first section of the book, "In the Beginning," along with other key areas that provide the foundation for new ingredients and products that are essential for understanding and leading innovation in our industry.

This chapter introduces the basic fundamentals of the principles of molecular biology and why cosmetic industry professionals must understand them. It is our opinion, based on the developmental path being taken by ingredient suppliers and formulators, that, like learning to effectively use social media in the Internet age, if you do not at least have a basic understanding of these concepts, you will be left behind.

Consider this analogy, which is quite prevalent at the time of this writing. When young children age three or so and older, and teenagers, are walking around with their iPads and iPhones, etc., and you—the adult, the parent, the seeker of "how do I text, or use Linkedin," etc.—are your resource for how to do IT. If you do not use that brilliant mind of yours to lead the knowledge pack rather than be a follower, then, my friends, your foreseeable contribution to the development of new cosmetic and personal care products will wither into dust and be blown away by the wind.

And Now, to the Heart of the Matter…

1.4.1 INTRODUCTION

The Human Genome Project revolutionized scientific research in the field of molecular biology. Many of the techniques and gene interaction knowledge base currently in use are the result of the project. The cost and time to conduct such studies continues to decrease, resulting in the generation of information relevant to the formulations chemist. Molecular cell biology investigates how cells develop, operate, communicate, and control their activities. Cells communicate with body tissue, which is composed of cells. Tissues communicate with other tissues and organs throughout the body. Generally the transfer of information between cells, tissues, and organs is through proteins. We now know that genes consisting of deoxyribonucleic acid (DNA) are responsible for biological structure, maintenance, and integration of cellular function. DNA indirectly controls the synthesis of many small molecules including proteins. DNA may be considered a storage form of genetic information. Gene expression is how cells "know" to make the right proteins at the right time in the right quantities.

1.4.2 PRINCIPLES OF MOLECULAR BIOLOGY

Amino Acids and Proteins: Their Role in Cell and Tissue Communication

Proteins are the working molecules of the cell; they carry out the program of activities encoded by genes. To do this a coordinated effort of many different types of proteins is necessary (1). The three-dimensional structure of a protein enables it to regulate concentrations of metabolites, cause cell motion, and provide structural rigidity to the cell. The spatial organization of proteins is critical in understanding how they work (1).

Proteins consist of amino acids, and there are only twenty amino acids from which proteins derive their structure. The three-dimensional structure of the protein is determined by the amino acid sequence. Amino acids can be classified primarily on their solubility in water, which is influenced by the polarity of their side chains. Amino acids with polar side groups tend to be found on the cell surface and make proteins soluble in aqueous solutions. Amino acids with nonpolar side groups avoid water and aggregate to form the water-insoluble core of the protein. Water-soluble amino acids have ionized or polar side chains. At neutral pH, arginine and lysine are positively charged; aspartic acid and glutamic acid are negatively charged and exist as aspartate and glutamate. These four amino acids are the major contributors to the overall charge of a protein (1). Histidine has a pKa of 6.8, the pH of cytoplasm in the cell.

Small shifts in the pH of the cell will change the charge of histidine side chains. The activity of numerous proteins is modulated by pH through protonation of histidine side chains. Asparagine and glutamine are uncharged and have polar amide groups with extensive hydrogen-bonding capacities. Serine and threonine are uncharged and have polar hydroxyl groups facilitating hydrogen bonding with other polar molecules. Hydrophobic amino acids have aliphatic side chains that are insoluble or slightly soluble in water. These amino acids tend to pack in the interior of proteins away from the aqueous environment. Cysteine, glycine, and proline have side chains with unique properties. The cysteine side chain contains a reactive sulfhydryl that can oxidize to form a disulfide bond to a second cysteine. Disulfide bonds are commonly found in extracellular proteins where they facilitate maintaining a folded structure. Glycine, the smallest amino acid, has a single hydrogen atom as its R group. Its small size allows it to fit into tight spaces. Proline and glycine may be found at locations on a protein’s surface where the chain loops back into the protein.

The Cell

All organisms are composed of cells. A cell is a membrane-bound unit that contains DNA and cytoplasm. A plasma membrane encloses each cell, separating its contents from its surroundings. The plasma membrane contains numerous proteins that are responsible for the ability of the cell to interact with its environment. For example, receptor proteins in the membrane interact with hormones and induce changes in the cell in response to the interaction. Transport proteins help molecules and ions move across the plasma membrane either from the membrane at the cell surface to inside the cell, or from inside the cell to the cell surface. Every cell contains DNA, which is the hereditary molecule containing the genes that code for the proteins being synthesized by the cell.

Cells found in animals referred to as eukaryotic cells contain numerous compartments termed organelles and smaller sac-like structures known as vesicles. The largest organelle in a eukaryotic cell is the nucleus, which is the repository of the genetic information that directs all the activities of a living eukaryotic cell. The nucleolus is an area found in the nucleus where intensive synthesis of ribosomal RNA is occurring. A nuclear envelope is located on the surface of the nucleus. The outer membrane of the nuclear envelope is continuous with the cytoplasm's interior membrane system called the endoplasmic reticulum. Scattered over the surface of the nuclear envelope are nuclear pores filled with proteins that act as molecular channels permitting certain molecules to pass into and out of the nucleus. Proteins moving into the nucleus may be incorporated into nuclear structures or catalyze nuclear activities; RNA and protein-RNA complexes are formed in the nucleus and exported to the cytoplasm. DNA of the eukaryotic cell is divided into linear chromosomes, which are fully extended into thread-like strands called chromatin. This arrangement allows proteins to attach to specific nucleotide sequences along the DNA. Without this protein interaction DNA could not regulate the day-to-day activities of the cell. Chromosomes are associated with packaging proteins called histones.

When a cell is ready to divide, the DNA coils up around the histones into a tight condensed structure; this initial aggregation is termed a nucleosome, and resembles a bead on a string (2). After cell division the chromosomes uncoil, permitting RNA polymerase—an enzyme that makes RNA copies of the DNA—to gain access to the DNA. RNA copies of DNA are the only way hereditary information in the DNA can be used to direct the synthesis of proteins. The eukaryotic cell is distinguished from plant cells with the presence of internal

membranes in the cell. The largest internal membrane is the endoplasmic reticulum (ER). The ER is composed of a lipid bi-layer embedded with proteins. The surface is embedded with ribosomes involved in protein synthesis. Proteins synthesize on the surface of the ER (termed rough ER because the surface appears pebbly, like the surface of sandpaper). These proteins contain special amino acid sequences called signal sequences. These protein sequences travel through the ER membrane to the interior of the ER and then move to a vesicle-forming system known as the Golgi apparatus, and is eventually released to the outside of the cell.

Eukaryotic cells contain a variety of vesicles. Lysosomes are membrane-bounded digestive vesicles that contain enzymes catalyzing the breakdown of proteins. Other vesicles, known as peroxisomes, contain the enzyme catalayse, which breaks down hydrogen peroxide into water and oxygen. The breakdown of hydrogen peroxide is important because hydrogen peroxide buildup in the cell is toxic. Mitochrondria are organelles containing proteins that carry out oxidative metabolism of the cell. They have their own DNA-containing genes that produce proteins essential to the mitochrondria's role as centers of oxidative metabolism. Most of the genes that produce the enzymes used in oxidative metabolism are located in the nucleus of the cell. The nucleus is the control center of the cell for direction of protein synthesis and cell reproduction. The nucleolus is the manufacturing site for ribosomal subunits, which are sites for rRNA synthesis, a process necessary for DNA replication. Ribosomes provide a framework for protein synthesis.

1.4.3 PROTEOMICS, GENOMICS AND EPIGENETICS

Protein Conformations and Cell Communication

Mammalian cells contain up to 10,000 different kinds of proteins (1). Proteins must be localized to the appropriate cellular membrane or aqueous compartment to function properly (Figure 1). Proteins are the working molecules of the cell; they carry out the program of activities encoded by genes. The structure of the protein gives rise to its function. The function of virtually all proteins depends on their ability to bind to other molecules, or ligands with specificity. There are numerous types of receptors on the cell surface, and each is essential for signaling between cells. Affinity refers to the strength of binding and specificity refers to the ability of a protein to bind one molecule in preference to another

molecule. In some cases a particular protein on one cell binds to a receptor protein on the surface of an adjacent cell, triggering differentiation.

Figure 1: Overview of cell receptors and cell signaling

Cell signaling can be divided into three stages.

1. Reception: A cell detects a signaling molecule from the outside of the cell. A signal is detected when the chemical signal (also known as a ligand) binds to a receptor protein on the surface of the cell or inside the cell.

2. Transduction: When the signaling molecule binds the receptor, it changes the receptor protein in some way. This change initiates the process of transduction. Signal transduction is usually a pathway of several steps. Each relay molecule in the signal transduction pathway changes the next molecule in the pathway.

3. Response: Finally, the signal triggers a specific cellular response.

Source: Overview of Cell Signaling. http://creativecommons.org/ns#" xmlns:dct="http://purl.org/dc/terms/" about="http://www.hartnell.edu/tutorials/biology/signaltransduction.html

Available at: http://www.hartnell.edu/tutorials/biology/signaltransduction.html

Signal molecules are designated, endocrine, autocrine, or paracrine depending upon the distance over which the signal acts. Membrane-bound proteins on a neighboring cell can also signal to each other. In endocrine signaling the signaling molecules, or hormones, act on target cells distant from their site of synthesis. In paracrine signaling the molecules released are in close proximity to each other. In autocrine signaling cells respond to substances that they release themselves. There are compounds that may act by multiple types of signaling. Epidermal growth factor (EGF) is an example of a protein hormone synthesized in the plasma membrane. Membrane-bound EGF can bind to and signal an adjacent cell by direct contact. Cleavage by a protease releases secreted EGF,

which then acts as an endocrine signal on distant cells (1). There are four major classes of cell-surface receptors: 1) receptors with enzymatic regulatory function; 2) G-protein-coupled receptors, which activate or inhibit an enzyme that generates a specific second messenger or modulates an ion channel, causing a change in membrane potential; 3) ion channel receptors, which change the conformation of the receptor to enable specific ions to flow through the receptor resulting in a change of the electric potential across the cell membrane; and 4) tyrosine kinase-linked receptors, in which ligand binding stimulates formation of a dimeric receptor, which interacts with and activates one or more cytosolic protein tyrosine kinases. Receptors for many cytokines, interferons, and human growth factor are of this type. (See Figure 1)

GTPase is another protein category involved in signal transduction. This group of proteins functions as molecular switches that turn cell signaling on or off. GTPase proteins are regulated in different ways. Protein kinases work through phosphorylation of proteins. Animal cells contain two kinds of protein kinases, those directed towards tyrosine and those directed towards either serine or threonine. Protein kinases become active in response to the stimulation of signaling pathways. The catalytic activity of kinases is modulated by phosphorylation, by direct binding to other proteins, and by changes in the levels of various second messengers. Adapter proteins function as docking sites for other proteins and mediate transport steps of structural proteins in the cell.

Epigenetics

Revising the Paradigm in the Age of Genomics

Epigenetics is defined as somatically heritable states of gene expression resulting from changes in chromatin structure without alterations in DNA sequence. Epigenetic changes are involved in inflammation, obesity, insulin resistance, aging, immune disorders, and cancer. The previous paragraphs summarized cell signaling through numerous protein messengers that activate a cascade of molecular events within the cell and between cells. Many cell-signaling mechanisms are not well understood. It is increasingly becoming evident that cell signaling modifies gene expression of critical genes associated with physiologic and pathologic processes. More recent observations in the field of epigenetics indicate that epigenetic modifications can be influenced by external or internal environmental factors.

It is anticipated that the emerging field of **epigenetics** will dominate the field

of genetics for the next decade and beyond. “Epi,” from the Greek language, means “above or over.” Epigenetics, above genetics, is an influence that affects appearance without changing the DNA code. In other words it is an influence that can affect gene expression without causing a mutation in the DNA code. The mechanisms of epigenetic gene expression can be profiled using a variety of techniques. Commonly used techniques measure the regulation of translation or stability of messenger RNA (mRNA), DNA methylation, and histone modification. Virtually all biological pathways and diseases may have an underlying epigenetic component. The epigenome is dynamic; it exhibits changes during the aging process. As an individual ages, gene promoters become hypermethylated, and many of the age-related DNA methylation markers are also associated with disease. Epigenetics is discussed in more depth elsewhere in this text.

A key element of epigenetics is chromatin and its structure. Chromatin is a DNA complex organized into repeating units called nucleosomes. Chromatin is wrapped around the DNA. The degree of winding plays a role in gene regulation. When the winding pattern is altered by a chemical or environmental stimulus, the change in winding pattern is termed histone modification. Modification of histone winding may result in an altered gene expression. Histone modifications regulate DNA transcription, repair, recombination, and replication. They can alter local chromatin architecture. Histones. proteins found in the cell nuclei of animals, package and order the DNA into structural units called nucleosomes. Nucleosomes are the chief protein components of chromatin.

The best-understood and most commonly studied histone modifications are acetylation, phosphorylation, methylation, and ubiquitination. Histone modification regulates DNA transcription, repair, recombination, and replication. It can alter chromatin structure. DNA methylation is a biochemical process involving the incorporation of a methyl group to the cytosine or adenine on the DNA nucleotide. DNA methylation alters the gene expression in cells and plays a role in many forms of cancer. DNA methylation is involved in the regulation of many cellular processes, including chromosome stability, chromatin structure, embryonic development, and transcription.

A study investigating aging and chronic sun exposure related to epigenetic changes in skin found that DNA methylation plays a role in aging skin exposed to the sun (4). DNA phosphorylation is the addition of a phosphate group to a protein, resulting in a conformational change that initiates protein activation or

deactivation of DNA regulatory mechanisms. DNA acetylation involves the removal of the positive charge on the histones, thereby decreasing the interaction of the N termini of histones with the negatively charged phosphate groups of DNA. As a consequence, the condensed chromatin is transformed into a more relaxed structure that is associated with greater levels of gene transcription. Translation is the process of DNA transferring genetic information via RNA that is processed by the ribosome into a chain of amino acids that become functioning proteins termed messenger RNA (mRNA). Transcription is the protein folding of the resulting mRNA proteins. The changes in gene expression and protein expression are the biological markers measured.

1.4.4 APPLICATION FOR SKIN CARE

The Broader Perspective of Molecular Biology

All life depends on three molecules: deoxyribonucleic acid (DNA), which holds information on how the cell functions; ribonucleic acid (RNA), which acts to transfer information to different parts of the cell and provides the template to synthesize proteins; and proteins, which form enzymes that send signals to other cells to regulate gene activity. Proteins also form the body's major components. A common feature of all organisms is the ability to store chemical energy as adenosine triphosphate (ATP). Genetic information is encoded by DNA, and the genetic information is transcribed by RNA. Translation involves ribosomes that use proteins via shared metabolic pathways. Gene expression is regulated through transcriptional controls that are proteins acting on the region of the gene termed a promoter site. These proteins are termed transcription factors, repressors/inhibitors, or enhancers, based on their influence of the gene. This activity results in epigenic changes.

Skin is the primary interface between the body and the environment. It is the first line of defense against microbial pathogens, and against physical and chemical insults. There is a growing body of evidence suggesting that the immune responses in skin are important in the maintenance of homeostasis and occurrence of skin pathologies. Various cells present in the epidermis, including Langerhans, T-cells and macrophages, mast cells, and nerve-related cell types are also found in the dermis. The dermis is drained by lymphatic and vascular conduits through which migrating cells can traffic (3). Keratinocytes may be thought of as sensors of danger from pathogens, irritants, and other toxins. This

is carried out via numerous molecular pathways in skin. Activation of some of the receptors is through the inflammasome, which is a large multiprotein complex in the cell. Ultraviolet radiation activates inflammasomes in keratinocytes, leading to activation of various inflammatory pathways that in turn activate tissue-resident immune cells. Any type of barrier disruption, including UV light, trauma, irritants, or infection, triggers a coordinated immune response to maintain skin homeostasis. Skin-resident immune cells are important sentinels for homeostasis restoration and maintenance of normal cell activity.

Gene expression studies are currently providing insight into the biological mechanisms of skin aging and other aspects of skin health. The implication of these studies is that we have the capability to improve the appearance of aging skin through epigenic therapy. Skin hydration, barrier repair, renewal of the extracellular matrix, pigmentation, and human antioxidant capacity are examples applicable to skin care. The cost and the time to conduct epigenetic studies continues to decrease, resulting in the publication of numerous papers focused on skin hydration, barrier repair, renewal of the extracellular matrix pigmentation, antioxidant capacity, and certain skin cancers. Common conclusions in the papers suggest that “epigenic therapy” will revise skin care treatments, with additional strategies aimed at improving the appearance of skin. Nrf2 and AMPK signaling pathways are associated with epigenetic effects.

The Basics of Cell Signaling and Gene Expression Analysis

Transcription factors are a group of DNA-binding proteins that control which genes are turned on or off in the genome. They do so by binding to DNA and other proteins. Once bound to DNA, these proteins can promote or block the enzyme that controls the reading, or “transcription,” of genes, making genes more or less active. Frequently a specific cellular signal pathway can activate multiple transcription factors. The significance of this is that expression of a specific gene is under control of multiple transcription factors. Transcription factors are essential for the regulation of genes. For example, different genes turned on in liver cells than in skin cells. Different genes are turned on in cancer cells than in healthy cells. Through the action of transcription factors, the various cells of the body, which all have the same genome, can function differently. These proteins are so important to life that they are found in all living organisms. They play important roles in development, the sending of signals within the cell, and the events in a cell that lead to division and duplication, known as the cell cycle.

Several human diseases are linked to mutations in transcription factors, such as diabetes, autoimmune diseases, and cancer. Cytokines (cell motion) are signaling molecules that have key roles in several biological processes that include cellular growth, differentiation, gene expression, migration, immunity, and inflammation. Malfunction of cytokines can lead to a variety of diseases including arthritis, cardiac-related diseases, and cancer. Various cell types can secrete cytokines and other inflammatory mediators as part of an immune or inflammatory response. Gene expression analysis is the process by which information from a gene is used to direct the synthesis of a functional gene product, generally a protein. Gene expression analysis is the process of understanding the function of the gene, their protein products, and the complex regulatory network that affects biological processes of the cells.

Examples of Gene Expression Studies Relevant for the Cosmetic Chemist

Nrf2

Aging is a process that all living organisms experience. An aging human population is interested in products that promote health and maintain a younger-looking appearance. The molecular mechanism(s) of aging are not completely clear and are an area of intense molecular investigation. An area of current focus is on the Nrf2 signaling pathway. The Nrf2 signaling pathway is a mediator of multiple cell signaling cytoprotective pathways. It is expressed in numerous body tissues at different levels. It activates transcription of more than 200 genes crucial in the metabolism of drugs and toxins, signaling for protection against oxidative stress and inflammation. Nrf2 interacts with other key cell regulators including tumor suppressor protein 53 (p53) and nuclear factor kappa beta (NF-Kβ). These interactions are associated with age-related diseases (5). In 1956 Denham Harman postulated that reactive oxygen species (ROS) cause indiscriminate oxidative modification of cellular components leading to damage that cannot always be completely neutralized by antioxidants (6). Recent studies have resulted in producing data that question the validity of the Harman theory (7).

Many long-lived species of animals are found to have high levels of oxidative damage (8, 9). An emerging theory is that cellular stress resistance associated with extended aging tends to exist for numerous other nonoxidative stressors including heat, heavy metals, chemotherapeutic agents, dietary alterations, and xenobiotics (5). Another theory is that oxidative insult is just one factor of a multifactorial cytoprotective pathway that protects against cellular stressors

including synthesis of molecular chaperones, components of cell cycle surveillance, protein degradation, and oxidative stress. Nrf2 is a stress-sensing genetic transcription factor that appears to be a master regulator involved in many of these defense mechanisms (5). Gene expression studies have shown that phytochemicals work through the Nrf2 pathway. Sulforaphane, a component of broccoli, was found to be effective via this pathway (10). Nrf2 was shown to protect keratinocytes from ultraviolet A (UVA) irradiation by increasing the protein levels of Nrf2 in cell culture (11). Quercetin, resveratrol, caffeic acid, epicatechin, epigalocatechin, catechin chemical components found in polyphenolics are associated with Nrf2 activation (11). In summary it is hypothesized that long-lived species express higher levels of Nrf2. Nrf2 appears to be protective against numerous pathological conditions associated with reactive oxygen species (ROS) damage, inflammation immune responses, cell survival, and carcinogenesis (ROS).

Adenosine Monophosphate Activated Protein

Another signaling pathway potentially relevant to skin care is adenosine monophosphate activated protein (AMPK). AMPK is a master metabolic sensor and regulator of the cell, an enzyme that plays a role in cellular energy homeostasis. AMPK consists of three proteins that together make a functional enzyme. It is expressed in a number of tissues, including the liver, brain, skeletal muscle, and skin. AMPK has a key role in the regulation of cellular lipid and protein metabolism in response to stimuli, including physical exercise and changes in diet. The AMPK pathway interacts with other molecular pathways responsible for tumor formation and DNA damage repair (12). AMPK is switched on by metabolic stresses and various chemical compounds that cause a cellular energy imbalance. Energy status of the cell is critical for cell function, and AMPK has several downstream molecular targets that are modulated by changes in cell metabolism, cell growth, and other related functions that restore energy homeostasis to the cell. The AMPK pathway intersects with the Ras/PI3K/mTor and ERK pathways that are involved in tumor formation and cell growth. It also interacts with p53 and ATM pathways, which are tumor suppressor pathways and genomic gatekeepers (12). AMPK can be activated by resveratrol preventing hydrogen peroxide–induced premature senescence of keratinocyte cells when evaluated in human keratinocyte cell cultures (13). Another of its actions is to regulate the transcription of genes that function in the metabolism of glucose, fatty acids, and cholesterol. The AMPK signaling

pathway may also play a role in stimulating mitochondrial biosynthesis. In a keratinocyte cell culture study, resveratrol was found to activate AMPK and prevented the hydrogen peroxide–induced cellular senescence associated with cellular aging. The investigators note that cellular senescence is also linked with cancer in addition to aging (13). A variety of nutraceuticals and traditional medicines derived from plant products found in foods and beverages have been reported to activate AMPK in cells. In addition to resveratrol, epigallochatechin-3-gallate from green tea, curcumin, garlic oil, and berberines are reported in the literature (14).

1.4.5 (FUTURE PERSPECTIVES) CONCLUSION

Gene expression studies are providing a great amount of data that are not completely understood as applied to our health. While current knowledge of the use of gene expression is limited, the knowledge base is rapidly advancing. Published data indicate that bioactive ingredients have a biological effect that can be detected via various molecular biological assays using known markers. *In vitro* cell culture studies indicate that there may be a difference in biological activity depending upon the cell type studied. Further, it is hypothesized that there may be a difference in the efficacy of a biological active depending upon the existing state of the body when consumed or applied topically. An active may help to prevent a malignancy from developing; yet if applied or consumed after the malignancy has developed, it may in some cases have the opposite effect (12, 14).

In reviewing many of the published papers investigating gene expression, a common comment is “limitation of methodologies available to the investigator.” There are continuous variations in cells during the lifetime of an individual, and epigenic changes may be a consequence of changes in the cellular composition as a person ages over time. There are also synergistic effects that may affect the outcome of a study leading to conflicting data, depending on the variation of study protocol, even if minor. As research techniques in gene expression improve, there is no doubt that data interpretation will improve—leading to enhanced skin care products.

Figure 1 A schematic of an intracellular signaling pathway. Starting at the top, an extracellular signaling molecule binds with a receptor protein that then cascades a signal via intracellular signaling proteins that continue to cascade to target proteins, eventually resulting in modification of various cell activities as shown. Example modifications are altered metabolism of the cell, altered gene expression, and shape or movement of cells. From Molecular Biology of the Cell, 4th edition A.B. Johnson *et al.* (New York, Garland Science, 2002).

GLOSSARY

Biological Markers

A specific landmark that can be identified. It may be a substance, physiological characteristic, gene, *etc.* that indicates, or may indicate, the presence of disease or a physiological abnormality.

Chromatin

The material of which the chromosomes of organisms other than bacteria (i.e., eukaryotes) are composed.

DNA methylation

The modification of a strand of DNA after it is replicated, in which a methyl (CH_3) group is added to any cytosine molecule that stands directly before a guanine molecule in the same chain. Since methylation of cytosines in particular regions of a gene can cause that gene's suppression, DNA methylation is one of the methods used to regulate the expression of genes.

Endoplasmic reticulum

A membrane network within the cytoplasm of cells involved in the synthesis, modification, and transport of cellular materials.

Epigenetics

The study of inherited changes in appearance or gene expression that may be associated with diet and lifestyle.

ERK, MAPK, the MAPK/ERK pathway

A chain of proteins in the cell that communicates a signal from a receptor on the surface of the cell to the DNA in the nucleus of the cell. The signal starts when a signaling molecule binds to the receptor on the cell surface and ends when the DNA in the nucleus expresses a protein and produces some change in the cell, such as cell division. The pathway includes many proteins, including MAPK (Mitogen-activated protein kinases, originally called ERK, Extracellular signal-regulated kinases), which communicate by adding phosphate groups to a neighboring protein, which acts as an "on" or "off" switch.

Gene expression

Conversion of the information encoded in a gene first into messenger RNA and then to a protein.

Histones and histone modification

Low-molecular-weight proteins that form a complex with DNA in the chromatin and function in regulating gene activity. Histones are highly alkaline proteins found in eukaryotic cell nuclei that package and order the DNA into structural units called nucleosomes. Chromosomal processes such as transcription are

influenced by a variety of post-translational modifications to histones, including acetylation, phosphorylation, methylation, and ubiquitination. These modifications may act alone or in concert in a context-dependent manner to facilitate or repress chromatin-mediated processes.

Homeostasis

Homeostasis is the equilibrium of the internal environment within an organism. Disturbances in homeostasis cause decreased function of the cell and organism. It is the drive for efficiency of the cell, tissue, and body.

Inflammasomes

Large intracellular multiprotein complexes that play a central role in innate immunity.

Interferon (IFN)

Proteins made and released by host cells in response to the presence of pathogens such as viruses, bacteria, parasites, or tumor cells. They allow for communication between cells to trigger the protective defenses of the immune system that eradicate pathogens or tumors. IFNs belong to the large class of glycoproteins known as cytokines. Interferons are named after their ability to “interfere” with viral replication within host cells. IFNs have other functions: they activate immune cells, such as natural killer cells and macrophages; they increase recognition of infection or tumor cells by up-regulating antigen presentation to T-lymphocytes; and they increase the ability of uninfected host cells to resist new infection by virus. Certain symptoms, such as aching muscles and fever, are related to the production of IFNs during infection.

Ion channels

Ion channels are crucial components of living cells. Situated in the cell membrane, they allow ions to pass from one side of the membrane to the other.

Ligands (protein binding)

In molecular biology, a ligand (from the Latin ligandum, *binding*) is a substance (usually a small molecule) that forms a complex with a biomolecule to serve a biological purpose. In a narrower sense, it is a signal-triggering molecule, binding to a site on a target protein.

Lysosomes

Cellular organelles that contain acid hydrolase enzymes that break down waste materials and cellular debris. They can be described as the stomach of the cell. They are found in animal cells, while their existence in yeasts and plants is disputed.

mTOR

A protein that helps control several cell functions, including cell division and survival, and binds to rapamycin and other drugs. mTOR may be more active in some types of cancer cells than it is in normal cells. Blocking mTOR may cause the cancer cells to die. It is a type of serine/threonine protein kinase. Also called mammalian target of rapamycin.

Molecular chaperones

A large group of unrelated protein families whose role is to stabilize unfolded proteins, unfold them for translocation across membranes or for degradation, and/or to assist in their correct folding and assembly.

mRNA (messenger ribonucleic acid)

The type of RNA that codes for the chemical blueprint for a protein during protein synthesis.

Oxidative metabolism

Oxidative metabolism is often referred to as cellular respiration, the process during which chemical bonds of molecules such as glucose are converted into energy that life can use on a cellular level. It is referred to as “oxidative” because oxygen is a primary component of respiration. In the oxidative metabolism of glucose, for instance, glucose and oxygen combine to produce carbon dioxide, water, and energy. Oxidative metabolism occurs in gradual steps that convert the energy in bonds into chemical energy stored in adenosine triphosphate (ATP). ATP’s bonds carry energy throughout cells, releasing it when enzymes catalyze reactions.

Peroxisomes

A type of enzyme package similar to lysosomes. They are small vesicles found around the cell. They have a single membrane that contains digestive enzymes for breaking down toxic materials in the cell. They differ from lysosomes in the

type of enzyme they hold. Peroxisomes hold on to enzymes that require oxygen (**oxidative enzymes**). Lysosomes have enzymes that work in oxygen-poor areas and lower pH. Peroxisomes absorb nutrients that the cell has acquired. They are very well known for digesting **fatty acids**. They also play a part in the way organisms digest **alcohol** (ethanol). Because they do that job, you would expect liver cells to have more peroxisomes than most other cells in a human body. They also play a role in cholesterol synthesis and the digestion of amino acids.

P53 (also known as protein 53 or tumor protein 53)

A tumor suppressor protein that in humans is encoded by the TP53 gene. P53 is crucial in multicellular organisms, where it regulates the cell cycle and thus functions as a tumor suppressor that is involved in preventing cancer. As such, p53 has been described as “the guardian of the genome” because of its role in conserving stability by preventing genome mutation.

PI3K (PI3K/AKT/mTOR pathway)

An intracellular signaling pathway important in apoptosis and hence cancer. http://en.wikipedia.org/wiki/PI3K/AKT/mTOR_pathway - cite_note-7. The PI3K/AKT/mTOR pathway is activated by IGF-1 and has a number of downstream effects that either promote protein synthesis or inhibit protein breakdown. PI3K activation activates AKT, which activates mTOR.

RAS

A protein belonging to a large super-family of proteins known as “low-molecular-weight G-proteins.” These proteins are called “G-proteins” because they bind guanine nucleotides (GTP and GDP). They are called “low-molecular-weight” to distinguish them from another, distinct, clan of guanine nucleotide-binding proteins, the heterotrimeric G-proteins.

Somatically heritable

A somatic epitype is a nonheritable epigenetic alteration in a gene. It is similar to conventional epigenetics in that it does not involve changes in the DNA primary sequence. Physically, the somatic epitype corresponds to changes in DNA methylation, oxidative damage (replacement of GTP with oxo-8-dGTP), or changes in DNA-chromatin structure that are not reversed by normal cellular or nuclear repair mechanisms. Somatic epitypes alter gene expression levels without altering the amino acid sequence of the expressed protein. Current

research suggests that somatic epitypes can be altered both before and after birth, and this alteration can be in response to exposure to heavy metals (such as lead), differences in maternal care, or nutritional or behavioral stress. There is no indication that somatic epitypes are heritable in a conventional epigenetic fashion. Some research suggests that methylation levels (and gene expression) can be reversed for some somatic epitypes by alterations in environmental factors such as diet.

Transcription

The first step of gene expression, in which a particular segment of DNA is copied into RNA by the enzyme, RNA polymerase. Both RNA and DNA are nucleic acids, which use base pairs of nucleotides as a complementary language that can be converted back and forth from DNA to RNA by the action of the correct enzymes.

Xenobiotics

A chemical that is found in an organism, but is not normally produced or expected to be present in it. It can also cover substances that are present in much higher concentrations than are usual. Specifically, drugs such as antibiotics are xenobiotics in humans because the human body does not produce them itself, nor are they part of a normal diet. Natural compounds can also become xenobiotics if they are taken up by another organism, such as the uptake of natural human hormones by fish found downstream of sewage treatment plant outfalls, or the chemical defenses produced by some organisms as protection against predators. However, the term xenobiotics is very often used in the context of pollutants such as dioxins and polychlorinated biphenols and their effect on biota, because xenobiotics are understood as substances foreign to an entire biological system, i.e., artificial substances, which did not exist in nature before their synthesis by humans.

REGULATORY REQUIREMENTS, INTELLECTUAL PROPERTY AND ACHIEVING GLOBAL MARKET SUCCESS FOR COSMETIC PRODUCTS

REGULATORY REQUIREMENTS, INTELLECTUAL PROPERTY AND ACHIEVING GLOBAL MARKET SUCCESS FOR COSMETIC PRODUCTS

Co-Editors' Introduction
Co-Editors

Ruud Overbeek and Meyer R. Rosen

Part 2 of this book is unique since it covers the essential "nontechnical" information needed for achieving product success in a global environment. We have stepped out of the "normal" mode of presenting the technological aspects one might first expect, and thoughtfully placed this information here in recognition and emphasis that the technical aspects of ingredients are, of course, not the only areas of importance to achieving the goal of a successful product.

Once you have a stable product that works, looks good, and goes on well (all of which is covered later in this book), it is imperative that cosmetic and personal care professionals be aware of the rapidly changing world of regulations as well as making sure their technology is appropriately covered by patents.

We recognize that the regulatory environment is ever-changing and, after an overview of this area, we first cover thoughts on how to survive and thrive in this turmoil. We then turn to looking at what it currently takes to successfully market one's products in the different geographical areas. Finally, we cover the essentials of global patenting in general and then by geographical area.

GLOBAL REGULATORY DEVELOPMENTS'THE NEED TO KNOW

For centuries, humankind has utilized cosmetics to enhance or alter physical

appearance, negotiate conceptions of femininity or masculinity, combat external manifestations of aging, and assert social status. This pursuit of beauty is a virtually timeless and universally enduring endeavor. the CTFA President's Message in the Cosmetic, Toiletry, and Fragrance Association (CTFA) 2005 Annual Report noted the wide reach of the industry and its potential for expansion. "In an era of globalization," the president stated, "we are truly one of the world's most global industries. Our products and our innovation know no boundaries. Whether it's Bangkok or Beijing, Baton Rouge or Baghdad, the products that we make are the products that women and families use every single day."

In addition to the global expansion regarding cosmetics for women, the men's cosmetic market is also growing exponentially. Beyond product efficacy, the highest priority for personal care products and cosmetics companies is the safety and health of consumers who use their products. To be able to support health, safety, and global expansion goals, the industry has a constant need and duty to inform itself of existing regulations, by geographical area. Further, it must cope with the seemingly endless evolution of newly developed and emerging changes in global regulatory developments.

Separately, in order to have a chance of success in each global market area, as well as each product category, the industry—ranging from ingredient developers, new product manufacturers, and claim writers—has an unavoidable need to understand the drivers for local and global regulation in order to be able not only to address, but also contribute to and impact the development of regulations. This challenge is a key step towards global alignment and regulatory harmonization.

Since regulatory hurdles affect cross-border trade of goods, reduce global competitiveness, and may harm manufacturers of cosmetics and personal care products, a reduction of international regulatory burdens will allow manufacturers improved access to foreign markets. Crossing these hurdles successfully is a key to global economic health. While regulatory harmonization has a positive impact for the protection of public health and safety, it also offers many benefits to both regulatory authorities and the cosmetics industry. The development of harmonized guidelines would streamline the regulatory assessment process and reduce product and ingredient development times and resources needed. Such harmonized guidelines prevent duplication and minimize use of *in vivo* testing without compromising safety and effectiveness.

The movement towards harmonization has recently been addressed among the

International Cooperation on Cosmetics Regulation (ICCR), an international group of regulatory authorities for cosmetics from Canada, the European Union, Japan, and the United States. The group has held multiple meetings to discuss issues related to cosmetics and cosmetic-like drug/quasi-drug products. This group seeks to promote regulatory convergence, while maintaining the highest level of global consumer protection and minimizing barriers to international trade. ICCR has chosen to include members of consumer organizations and industry associations, with an interest in regulatory issues involving cosmetics. Meetings have focused on key regulatory issues affecting the industry in general:

- Alternatives to Animal Testing
- *In silico* (computer) Prediction Models for Safety Assessment
- Nanomaterials
- Trace Impurities
- Endocrine Disruptors
- Allergens

At this time, the highest-priority topic for regulatory professionals in the cosmetics industry is the discussion around animal testing and alternatives to animal testing. This discussion includes the use of predictive models as well as *in vitro* testing methods. Historically, safety testing of chemicals has relied heavily on animal tests. However, in view of consumer pressure, and regulatory recognition of the lack of humaneness in testing on animals, this approach is in the process of being revolutionized. Today, and in the near future, safety assessment of chemicals will rely increasingly on pathway-based toxicity information largely informed by advanced, human-relevant, non-animal tests that are predictive of human health and safety.

The EU (European Union) has recently phased out the use of animals for cosmetics testing, culminating in a ban on the marketing of animal-tested products in 2013. China's Food & Drug Administration (CFDA) has announced that effective June 2014, China plans to remove its mandatory animal-test requirements for domestically manufactured cosmetic products. Initially the new rules will only apply to cosmetics manufactured in China. However, the CFDA has stated that, once the new system has been established, it may be expanded to include imported products and certain "special use" cosmetics as well. Chinese companies producing "non-special-use cosmetics," including shampoos and skin creams but not hair dyes, sunscreens, or other products with biological activity, will be exempt from carrying out animal tests. Manufacturers will now have the

option to substantiate product safety using existing safety data for raw ingredients, or European Union-validated non-animal tests. This would be a major step towards removing trade barriers between China and the EU. Clearly, legislative endeavors are underway to ensure more consistency between European and other markets, but this topic remains a major area of concern for companies wishing to sell products globally. To effectively address concerns about the safety of cosmetic ingredients, new regulations and harmonization should allow for the use of human-relevant, non-animal test methods. The development of such tests will not only provide international market security, but will help drive regulatory science forward.

The rapidly expanding field of Nanotechnology may be considered a second important area. Driven by health and environmental concerns, legislation is being introduced globally in an effort to "control" this new, exciting, efficacious, and emerging technology. As a result, the subject of nanomaterials has formed part of the recast EU cosmetic regulations and is being seriously discussed in various other countries. According to EU Regulation (EC) No. 1223/2009, nanomaterials are defined as insoluble or biopersistent and intentionally manufactured materials with one or more external dimensions, or an internal structure, on the scale from 1 nm to 100 nm. The European Union's Commission sees in particular a need to better understand whether and how insoluble nanoparticles are used in cosmetic applications and has therefore agreed with cosmetic industry associations that it will set up an inventory of current applications of nanotechnology in cosmetic products together with the regulatory authorities from the U.S., Canada, and Japan. Results of this work will be assessed by the four authorities. Such measures are to help strengthen in-market control of products containing nanoparticles.

In the 2012 FDA Draft Guidance for Industry Safety of Nanomaterials in Cosmetic Products, the FDA summarized that inclusion of nanomaterials, or a change in the nanomaterials used, might affect the quality, safety, effectiveness, and/or public health impact of a nano-based product. Therefore, data needs and testing methods should be evaluated accordingly to address the unique properties and function of the nanomaterials used in cosmetic products. This need extends as well to the questions that continue to remain about the applicability of traditional safety testing methods to products that involve nanotechnology. Further, the FDA expects that the science surrounding nanomaterials will continue to evolve and will be used in the development of new testing methods. Although the FDA has not adopted a formal definition of "nanotechnology,"

“nanoscale,” or related terms, it has stated that the term is perhaps most commonly used to refer to the intentional manipulation, manufacture, or selection of materials that have at least one dimension in the size range of approximately 1 to 100 nanometers.

It is expected that the above topics, as well as other “hot” topics listed by the International Cooperation on Cosmetics Regulation (ICCR), will continue to play an important role in regulatory drivers and discussions. Discussion of such hot topics has especially reached a new level of impact with the emergence of social media. Also contributing to the acceleration of the discussion is an ever-growing, globally spread, public, social, regulatory, and political awareness that is expected to push faster regulatory change and possibly global harmonization. Any bad practice, emerging issue, or discussion about (the need for) new regulation will be very promptly published across social media, which can consequently oblige the regulator and industry to control, add, or remove ingredients from products and applications. Therefore, it is a prerequisite for any professional in the cosmetics industry to understand the regulatory framework and the potential social, political, and economic drivers for regulation in key economies around the globe.

This Section of the book has been carefully placed “up front” to insure that our industry *mus*t be aware of the significant impact of changing global regulations, as well as the need for an in-depth understanding of intellectual property matters in an environment that requires rapid evolution—nay, revolution—in products that really work and are safe and acceptable in the changing environmental context.

Thus, our belief is that this chapter is a must read for those industry professionals seeking globalization and desiring harmonization while pursuing the safety and health of consumers who use their products—be they “chemical-based,” “natural,” nano-type, or cosmeceutical—all of which may have biochemical impact on consumers.

ACHIEVING GLOBAL MARKET ACCESS-FOCUS ON RUSSIA AUTHOR

Ramzia Lefebvre Technical Manager for Russia and Customs Union Certification
INTERTEK FRANCE
Government & Trade Services

ABSTRACT

The expansion of the cosmetic and personal care market to all areas of the globe is indicative of the thirst of the peoples of the earth to look good, feel good, and have a healthy aging process. New markets beckon the world's ingredient developers, marketers, and product manufacturers for the need to expand into these "new" markets. Along with the development of new products for new needs, safety issues and regulations have proliferated. The bottom line here is that if a company wants to sell in a far-flung market, it must become knowledgeable about the changing requirements being promulgated by various countries. One such "new" market is Russia. The Russian and Customs Union markets are highly attractive for cosmetic manufacturers and exporters, as the demand for cosmetic goods increases by 5 or more percent each year. Actually, according to experts of the Russian press agency "Credinform," the annual growth rate could exceed 15% until 2015. As stated in the agency's study, import growth is associated not only with a steady growth in demand for foreign-made cosmetics, but also with a reduction of customs duty on imported products after Russia's WTO accession. The Russian market for cosmetics is one of the most dynamic in the world.

In this chapter we provide a detailed description of requirements for companies wishing to gain a part of this lucrative market, and have designed our description in the form of a series of questions and answers relevant to those seeking access to the expanded Russian market.

2.3.1.1 INTRODUCTION

Much anticipated by the cosmetic world and generating many questions during the two last years, new Technical Regulation No. TR TC 009/2011 on the “Safety of perfumery and cosmetic products” (approved on 23.09.2011 by Customs Union Commission’s Decree no. 799) finally came into force on July 1, 2012. This document became applicable within the whole Customs Union of Russia, Belarus, and Kazakhstan.

We will discuss the general objectives of the Customs Union (hereafter CU) and the differences between the “old” procedure and the new one. We will address whether the new rules simplify access to Russian and CU markets; how

the new rules are different from European requirements; and how they will affect exports of cosmetics to Russia.

2.3.1.2 WHAT IS THE CUSTOMS UNION AND WHAT IS ITS AIM?

The new regulation does not concern only Russia, but the whole territory of the CU.

The Customs Union between Russia, Kazakhstan, and Belarus came into existence on January 1, 2010. These three states became one region by economic integration and removal of customs borders between Belarus, Kazakhstan, and Russia beginning on July 1, 2010. During the first stage of the integration process, the aim of the Customs Union was to create:

- Common customs tariffs without customs duties inside member-states
- Common customs code
- Other joint measures for foreign trade regulations

From January 1, 2012, the three states moved to the next step and established a single economic area through a number of inter-state agreements such as: “On single principles and rules of technical regulation”; “On single principles of regulating intellectual property rights protection”; “On coordinated macroeconomic policy”; “On single principles and rules of competition” and others. These principles were established in order to build a single market with a single macroeconomic policy that would simplify goods, services, capital, and manpower circulation.

The first joint document of the CU was issued in 2010, establishing unified hygienic requirements and unified assessment rules for various goods, including cosmetics: “Unified Sanitary-epidemiological requirements of the Customs Union” (also known as Decree no. 299 dated 28.05.2010). This document set up mandatory State Registration for the Customs Union instead of previous sanitary-epidemiological legislation in Russia.

Development and approval of the Technical Regulations of Customs Union for different categories of products, including cosmetics, have been the continuity of this reform.

2.3.1.3 WHAT WERE THE OLD REQUIREMENTS AND PROCEDURES OF PRODUCT CONFORMITY ASSESSMENT

AND HOW HAVE THEY PROGRESSED TO DATE?

1. Prior to July 1, 2012

Before July 1, 2012, the majority of cosmetic products (with the exception of fragrances) were subject to a two-stage conformity assessment:

1. Customs Union State Registration
2. GOST R Declaration of Conformity of Russia or GOST R Customs Union Certificate of Conformity

with slight difference for fragrances, which used to be subject to:

1. Customs Union Sanitary Control (testing according single CU requirements);
2. GOST R Declaration of Conformity of Russia or GOST R Customs Union Certificate of Conformity.

Both State Registration and Sanitary Control were done according to Unified Sanitary Requirements of the Customs Union (Decree no. 299).

Once the products passed the second step, i.e., GOST R certification, they used to be marked by the GOST R Mark of Conformity to demonstrate product compliance with the applicable Russian standards.

Relevant authorities for both steps of certification were:

The double conformity assessment takes its origin from the requirements for the Sanitary and GOST, provided by the Ministry of Health and Social Development and the Ministry of Industry and Trade respectively. The basic concern of both authorities and of the Russian certification system was to protect the safety, health, and environment of the Russian people and to prevent dangerous and noncompliant imported products from being placed on the Russian market. Consequently many products entering the territory of the

Russian Federation required double conformity assessment in order to:

1. Confirm that the products met Russian safety standards relative to the environment, life, and health of population

And in practice to:

1. Enable goods pass to through Russian customs
2. Enable goods to be used, sold, or marketed on Russian territory

Assessment documents issued according to the old legislation are still valid until July 1, 2014.

2. Since July 1, 2012

With introduction of the new Technical Regulation as of July 1, 2012, the function and aim of assessment documents remain the same. By contrast, the dual compliance system has been abolished. As of July 1, 2012, only one of following assessment documents is required:

- either CU State Registration
- or CU TR Declaration of Conformity

This topic is expounded in the next chapter.

2.3.1.4 OVERVIEW OF THE NEW CUSTOMS UNION TECHNICAL REGULATION "ABOUT SAFETY OF PERFUMERY AND COSMETIC PRODUCTS"

1. Definition of perfumes and cosmetics according to CU Technical Regulation

Perfumes and cosmetics are defined as "a substance or preparation intended to be applied directly on various external parts of the human body (epidermis, hair, nails, lips, and external genital organs), or on the teeth and the mucous membranes of the oral cavity with a single or primary purpose to cleaning them, changing their appearance, perfuming them, and/or correcting body odors and/or protecting them and/or keeping them in good condition and/or caring for them."

2. Conformity assessment documents

As noted previously, the new Technical Regulation came into force on July 1,

2012. It is designed to unify certification requirements for the member states and to remove the double assessment system.

This Technical Regulation suggests two conformity assessment documents: **State Registration** or TR **Declaration of Conformity**.

a) State Registration

According to the text of the Technical Regulation, only a small list of products is subject to State Registration (higher-risk products). They include the following 13 categories:

1. artificial tanning products (autobronzants)
2. skin whitening (lightening) products
3. cosmetic products for tattoos
4. personal hygiene products
5. products for protection of skin from harmful industrial factors
6. cosmetic products for children
7. hair colorants, bleaches, and highlights
8. hair perms and hair straightening products
9. products made using nanomaterials
10. products for hair removal
11. peelings
12. products for dental and oral hygiene containing over 0.15% fluorine (or over 0.05% for liquid products)
13. Dental bleaching agents containing hydrogen peroxide and other ingredients producing hydrogen peroxide, including carbamide peroxide and zinc peroxide in the concentration of hydrogen peroxide (as an ingredient, or produced) 0.1–6.0%

State Registration certificate can be issued in the name of the manufacturer only, without mention of Russian or CU importer/distributor. By this means, the certificate can be used for the whole territory of the Customs Union and for different importers/distributors, regardless of their location. Its period of validity is not limited.

Information on registered products is entered in the unified CU register of State registration certificates before products are imported into the territory of the Customs Union.

b) TR Declaration of Conformity to Customs Union

All other cosmetics are subject to a CU TR Declaration of Conformity.

Declaration of Conformity is issued on the name of a legal entity registered in the Customs Union (buyer, importer, or distributor) and for one specific contract between the exporter and the importer, so that its validity is limited to one client and to the duration of the contract.

For both documents, testing of products at a CU-accredited laboratory is required. Conformity assessment shall be done before entering the Customs Union territory.

Both the Declaration of Conformity and State Registration to Customs Union are issued for a single product or a group of similar products and are valid until the product name, formulation, or manufacturer are changed. Products can be grouped in one conformity document upon condition that they are produced by the same manufacturer; according to the same technical requirements; and have similar ingredients composition, hygienic specification, and usage. However, they may differ by insignificant differences without impact on the hygienic value (for instance: different form or volume of goods, color or aroma resulting from the use of coloring and flavoring agents).

Requirements for obtaining both documents were brought into line with the most demanding conditions (i.e., those applied to previous State Registrations). All documents for conformity assessment must be presented with Russian legalized translations.

3. Requirements for perfumes and cosmetics

Safety of perfumes and cosmetics is ensured by a set of requirements for:

1. composition (*CU TR Appendices 1 to 5: lists of regulated ingredients*)
2. physical and chemical parameters (*Appendix 6*)
3. microbiological parameters (*Appendix 7, Article 5, item 5 of CU TR*)
4. the contents of toxic elements (*Article 5, item 5 of CU TR*)
5. toxicological parameters (*Appendix 7*)
6. clinical parameters (*Appendices 9, 10*)
7. production (*Article 5, item 7 of CU TR*)
8. consumer packaging (*Article 5, item 8 of CU TR*)
9. product marking (*Article 5, item 9 of CU TR*)

4. Labeling requirements

Perfumes and cosmetics labeling (marking) is "consumer information in the

form of inscriptions, digital, color, and pictograms to be applied to the consumer containers, label, sticker."

Marking of perfumes and cosmetics should contain the following information:

- Name, designation (if any) of perfumery and cosmetic products
- Intended use of perfumery and cosmetic products, unless it is clear from the product name
- Cosmetics for children should have the relevant information in the labeling
- Manufacturer's name and location (legal address, including country)
- Country of manufacture (if the country where the manufacturing facilities are located differs from the manufacturer's legal address)
- Name and location (legal address) of an enterprise authorized by the manufacturer to accept claims from the consumer (manufacturer's authorized representative, importer) if the manufacturer does not accept the claim itself in the territory of the member state of the CU
- Nominal amount (volume or mass) of product in a consumer pack (for solid toilet soap—the nominal mass of a piece, at the time of packaging), except for perfumery and cosmetic products with nominal mass less than 5 gr, or less than 5 ml nominal volume, or free samples of perfumery and cosmetic products
- Color and/or tone (for makeup products and coloring agents)
- Mass fraction of fluoride (% or mg/kg, or ppm) for oral hygiene products containing fluorine compounds
- Shelf life: manufacture date (month, year) and shelf life (months, years), or the notice "best before" (month, year) or "use before" (month, year)
- Description of storage conditions if different from the standard
- Special safety application measures (if necessary), including the warning information stated in Appendices 2–5 of the Technical Regulation
- Batch number or special code allowing identification of the perfumes and cosmetics
- Methods of application of the perfumes and cosmetics, which if not provided can lead to misuse by a consumer of the perfumes and cosmetics
- List of ingredients
- Ethyl alcohol by volume (%)

If the perfumes and cosmetics are accompanied with forwarding information, the products are marked with a graphic symbol of a hand on an open book:

All information must be written in the official language of the member state of the Customs Union in which the product will be marketed: Russian for Russia and Belarus, and Russian with Kazakh for Kazakhstan.

5. Mark of conformity

As per **Decision of the Customs Union Committee N 711 dated 15.07.2011 "On the uniform market circulation marking of products within the Customs Union,"** products that are certified according to the requirements of the Technical Regulations should bear the EAC conformity mark of the Customs Union (EAC stands for EurAsian Conformity), and no longer the Russian Gost-R mark.

Mark of conformity can be placed on each product, package, or accompanying documents in any reasonable way to make it indelible and clear.

Mark of conformity can be placed *only* after successful certification and *before* putting the product on the market. Minimum size allowed is 5 mm.

EAC

2.3.1.5 HOW DIFFERENT ARE THE NEW RULES FROM EUROPEAN REQUIREMENTS?

For cosmetic manufacturers and exporters, the new Technical Regulation provides a double advantage: bringing Russian regulation closer to regulation in the European Union, and ending "the dual compliance system." Furthermore, this Technical Regulation also includes Belarus and Kazakhstan, two other members of the Customs Union, thus allowing access to more markets with one set of documents. Actually, this is true for State Registration but not for Declaration of Conformity, which is linked to specific importers or distributors.

In particular, one of the aims of cosmetic Technical Regulation was to harmonize requirements on cosmetic products for member countries of the Customs Union and make them more aligned with European rules, from the

manufacturing process to product labeling. The content and structure of these regulations have been inspired by both the European Directive 76/768/EEC and the European Regulations 1223/2009. The definition of cosmetics and the lists of regulated ingredients are almost identical (lists of substances prohibited in cosmetics, restrictive list of substances that cosmetic products may contain only under certain conditions, and lists of the only substances that can be used in cosmetics as coloring agents, preservatives, or UV filters).

However, the text still contains many requirements specific to Russia and to member countries of the Customs Union.

These include:

- Maintaining the obligation to confirm product compliance by a third party (Russian/CU-accredited laboratories and certification bodies)
- Maintaining animal testing
- Indicating expiry date and date of manufacture of the product
- Affixing Eurasian Conformity Mark (EAC)
- Indication of fluorine contents by weight (% or mg/kg or ppm) for oral hygiene products
- Setting limits for testing parameters in each category of products

In such manner, the Technical Regulation specifies the pH value of products, their microbiology, and various other aspects not detailed in European Directive 76/768 and its amendments, or in Regulation (EC) No. 1223/2009, which have replaced the Directive as of July 2013.

For instance, a **facial or body cream** or **liquid mascara and eyeliner** are regulated by the following:

	Facial or body cream	**Liquid mascara and eyeliner**
Physicochemical requirements		
pH value	5,0–9,0	5,5–8,5
Content of toxic elements:	perfumes and cosmetics containing natural herbal or natural mineral raw materials in amount exceeding 1% shall show the content of toxic elements not exceeding:	
arsenic	5.0 mg/kg	
mercury	1.0 mg/kg	
lead	5.0 mg/kg.	
Microbiology		
Total aerobic mesophilic and optionally anaerobic		

count: *CFU – colony-forming units per 1 g or 1 ml of a product	10^3 and less CFU* per 1 g (ml)	10^2 and less CFU* per 1 g (ml)
Candida albicans:	Not allowed in 0.1 g or 0.1 ml	Not allowed in 0.5 g or 0.5 ml
Escherichia coli:	Not allowed in 0.1 g or 0.1 ml	Not allowed in 0.5 g or 0.5 ml
Staphylococcus aureus:	Not allowed in 0.1 g or 0.1 ml	Not allowed in 0.5 g or 0.5 ml
Pseudomonas aeruginosa:	Not allowed in 0.1 g or 0.1 ml	Not allowed in 0.5 g or 0.5 ml
Toxicology:		
Skin irritant action:	0 points (none)	0 points (none)
Action on mucous membranes:	0 points (none)	0 points (none)
general toxic action measured by alternative methods *in vitro*:	none	none
Clinical testing:		
Irritant action:	0 points (none)	0 points (none)
Sensitizing action:	0 points (none)	0 points (none)

Similarly to these examples, each category of products has its own requirements. Categories vary depending on the type of testing. For example, cosmetics are divided into 33 categories for pH value, into three groups for microbiological requirements, into 21 categories for toxicological requirements, and into 23 categories (including oral hygiene products) for clinical requirements.

As can be seen from the above, the Technical Regulation requires several additional constraints compared to the rules of the European Union.

2.3.1.6 DO THE NEW RULES SIMPLIFY ACCESS TO THE COMBINED RUSSIAN AND CU MARKET? HOW DO NEW RULES AFFECT EXPORTS OF COSMETICS TO RUSSIA?

All cosmetic manufacturers exporting their products into Russia are expecting simplification of exportation rules and regulation requirements. In fact, the new Technical Regulation seems to simplify these procedures. However, experience

has shown that changes don't always mean simplification, as has been the case with the GOST R declaration of conformity in 2010. Presently, it is quite premature to confirm that simplification has resulted.

At this early stage of promulgation the introduction of new rules is accompanied by typical confusion among the main players involved. Thus, many issues continue to be discussed and amended. For instance, the following projects of amendments are currently under study:

- Rules for issuing of the Declaration of Conformity of Customs Union
- Rules for edition (filling out) of State Registration of Customs Union and its annexes
- Rectification of some terminology (e.g., definition of "peeling")
- Elaboration of support standards for testing methods, labeling, *etc.*

Only recently the authority responsible for application and verification of right application of the Technical Regulation in Russia was named. This function was entrusted to RosPotrebnadzor, the Federal Service for supervision in the area of consumer rights and welfare protection (RF Government decree no. 989 dated September 27, 2012), acting under the Ministry of Health. The decision was made three months after the Technical Regulation came into force. In the same manner, controls under right application of Technical Regulations have been recently assigned to the newly created state authority "Rossaccreditatsia" (Federal Accreditation Service).

The end product of these changes says that the rules are not yet completely fixed.

2.3.1.7 BUSINESS CLIMATE IN RUSSIA AND REFORMS—RUSSIA JOINED WTO

On December 16, 2011, after 18 years of negotiations, Russia was accepted as a World Trade Organization (WTO) member after final ratification in August 2012. In acceding to the WTO, Russia embraces a series of rules and commitments and would ensure that all legislation related to sanitary and phytosanitary measures, technical regulations, standards, and conformity assessment procedures comply with the WTO SPS (Sanitary and Phytosanitary Measures) and TBT (Technical Barriers to Trade) agreements. This should be the next step for facilitating international trade and in Russian efforts to make a more favorable entrepreneurial climate. Today this is evidenced by reducing customs duties for imported goods.

KINGDOM OF SAUDI ARABIA (KSA): COSMETICS AND PERFUMERY PRODUCTS: MARKET ACCESS AND REGULATIONS BY

Ms. Aurélie Bafoil

Cosmetic Regulatory Affairs Senior Analyst

Intertek Government and Trade Services

ABSTRACT

Saudi Arabia is a Middle East country, part of the Gulf Cooperation Council (GCC), which includes five other countries (Kuwait, United Arab Emirates, Qatar, Bahrain, and Oman).

In the past few years, the Saudi market has become a key and strategic market for cosmetic and perfumery products, quickly growing and constantly increasing, with particular demand for international luxury products and attracting the world industry. It is however a specific market, where prevailing social customs play a big role, and in which particular precautions need to be observed.

This section proposes an overview of the cosmetics regulations and of the procedures implemented for the control of perfumery and cosmetic products and its enforcement. It also identifies some key issues that are useful in drawing a risk analysis.

Kingdom of Saudi Arabia (KSA) Cosmetic and Perfumery Products: Market Access and Regulations TABLE OF CONTENTS

2.3.2.1 Regulatory Framework

2.3.2.1 REGULATORY FRAMEWORK

a. Cosmetic ruling authority

In the Kingdom of Saudi Arabia (KSA), the responsibility for regulation of cosmetic products conformity falls under the Saudi Food and Drug Authority (SFDA), which was created in 2003. Their Cosmetic Department was established in 2008 and is today primarily responsible for issuing regulations and controlling cosmetic product safety (for imported and locally manufactured products), but also for the development and update of standards and for cosmetovigilance.

The national standardization body (Saudi Arabian Standard Organization—SASO) transferred all activities linked to food, drug, and cosmetics standards to the SFDA in 2011; but it should be noted that although the responsibility for creating new standards now lies with SFDA, the applicable standards in Saudi Arabia are still the ones issued or adopted by SASO.

SFDA however published a draft version of its first own Cosmetic Safety Standard in December 2012. This standard is not approved yet, but it is aimed to replace all current SASO standards for cosmetics, including the specific product standards.

b. Cosmetic regulations and sanctioned standards

1. Sanctioned Safety Standard

SFDA official sanctioned standard is the Gulf standard: “GSO 1943/2009 –

Cosmetic Products Safety Requirements." This GSO Standard is equivalent to SASO 1953/2009; however, SFDA refers to the GSO reference in all their documents and communications.

This document is based on the EU Directive 76/768/EEC and follows the same structure:

→ Table 1: Substances that must not form part of the composition of cosmetic products
→ Table 2: Substances that must not be contained in cosmetic ingredients except subject to certain restriction and condition
→ Table 3: Coloring agents allowed for use in cosmetic products
→ Table 4: Preservatives that cosmetic products may contain
→ Table 5: Permitted UV filter that cosmetic products may contain

In addition to this standard, SFDA has published other ingredient prohibition/restrictions through its Guidance for Products Classification. This document includes additional restrictions that were previously decided by SFDA through circulars.

2. Guidance for Products Classification

This guideline "SFDA Guidance for Products Classification," published in 2012, determines rules for classifying products (from drugs to cosmetics) relative to definition of products, function, composition, and claims.

Among these rules, there are some significant ingredient restrictions to follow per product category. Cosmetic products are subject to the restrictions listed in the guideline, in addition to the tables under GSO 1943.

These additional restrictions for cosmetic products are:

1. Free of prohibited substances according to GSO 1943/2009 in addition to the following substances:
   a. Tretinoin (Retinoic acid) and its salts not permitted at any concentration)
   b. Hydroquinone (Dihydroxy Benzene)
   c. Triclosan not permitted at any concentration)
2. Compatible with restricted substances according to GSO 1943/2009 in addition to the following restricted substances:
   a. Vitamin A (Retinol) and its esters retinyl acetate, retinyl palmitate (permitted at concentrations equal to or less than 1%)
   b. Sulfur (permitted at concentration equal to or less than 2%)
   c. Urea (permitted at concentration equal to or less than 10%; cosmetics

intended to be diluted in bathwater may contain levels exceeding 10% urea)

d. Salicylic acid (permitted at different concentrations according to its role as shown in the following table):

Role	Salicylic Acid permitted concentration
Active Ingredient	≤ 3% in rinse-off hair products ≤ 2% in other products
Preservative	< 0.5%

e. Zinc oxide permitted at concentration less than 25% (unless it is used for a medical condition, in which case it will be classified as a drug)

f. Alpha-hydroxy acids (AHAs):

   a. Permitted at total concentrations equal to or less than 10%, with a pH equal to or greater than 3.5

   b. The inner and outer labels of all leave-on skin products containing AHAs at concentrations equal to or greater than 3% shall carry cautionary statements in Arabic and English to the effect: "Use only as directed," "Avoid contact with the eyes," "If irritation persists, discontinue use and consult a physician," "It is recommended that prior to exposure to the sun, users cover areas where AHAs have been applied with sunscreen," "Contact of the . . . product with the skin must be of limited frequency and duration."

   c. Preparations intended to be diluted in bathwater may contain levels of citric acid exceeding 10%.

Products falling under the above restrictions will generally be classified as low-risk health products and will be subject to listing at SFDA.

3. Product-specific standards

In addition to the general safety standard, some specific product standards still exist in the KSA. Even if these are not mandatory and not sanctioned officially by SFDA, it should be noted that they may be used for local assessment (for samples drawn by customs and tested in local laboratories). Some of these parameters may not be aligned with the SFDA-sanctioned standards. An acquaintance with the parameters included in these standards is therefore highly desirable in order to achieve a reliable risk analysis.

Example of specific parameters requested by a SASO standard: SASO

1512:2010 (equivalence GSO 1152:2010)

- ▶ pH value shall be in the range of 5–9,5.
- ▶ The total content of fatty substance shall be not less than 15% by mass.
- ▶ The water content shall be not more than 85% by mass.
- ▶ The utility date shall not be more than three years.

Note: All the SASO standards have equivalence at a GCC level with the GSO standards, which may be applicable in other countries within the GCC.

2.3.2.2 DEFINITION AND SCOPE OF APPLICATION

a. Definition

As per GSO 1943/2009, "Cosmetic Products—Cosmetic Products Safety Requirement," the written definition of a cosmetic product is identical to the European definition: *"Any substance or preparation intended to be placed in contact with the various external parts of human body (epidermis, hair system, nails, lips, and external genital organs) or with the teeth and the mucous membranes of the oral cavity with a view exclusively or mainly to cleaning them, perfuming them, changing their appearance and/or correcting body odors and/or protecting them or keeping them in good condition."*

This standard provides an illustrative list of products considered as cosmetic products, which include but are not limited to the following: – Creams, emulsions, lotions, gels, and oils for the skin (hands, face, feet, etc.) – Face masks (with the exception of peeling products) – Tinted bases (liquids, pastes, powders)

- – Makeup powders, after-bath powders, hygienic powders, *etc.*
- – Toilet soaps, deodorant soaps, *etc.*
- – Perfumes, toilet waters, and eau de cologne
- – Bath and shower preparations (salts, foams, oils, gels, etc.) – Depilatories
- – Deodorants and antiperspirants
- – Hair care products: hair tints and bleaches; products for waving, straightening, and fixing; setting products; cleansing products (lotions, powders, shampoos); conditioning products (lotions, creams, oils); hairdressing products (lotions, lacquers, brilliantines) – Shaving products (creams, foams, lotions, etc.)

– Products for making up and removing makeup from the face and eyes – Products intended for application to lips

– Products for care of teeth and mouth (mouthwash products containing alcohol are considered banned products) – Products for nail care and makeup

– Products for external intimate hygiene that do not contain ingredients that have antimicrobial activity – Sunbathing products

– Products for tanning without sun

– Skin-whitening products (except Hydroquinone-containing products) – Anti-wrinkle products

Note: There is a ban on alcohol in mouthwash; the decision to ban these types of products was taken by SFDA in 2011 due to the existence of permissible and available alcohol-free alternatives.

b. Classification

In 2012, the SFDA Drug sector issued another method to define the cosmetic by issuing the Guidance for Product Classification, which defines cosmetics but also the following product categories:

▶ Drug products

▶ Herbal products

▶ Health products

▶ Cosmetic products

The product category can be generally identified by referring to this Guideline; however, manufacturers can submit a classification request to SFDA to get an official Classification Letter to be sure of the product status.

The other categories are handled directly by SFDA locally and are subject to SFDA registration (for high-risk products: drug, herbal, and certain health products) or to SFDA listing (low-risk health products, cosmetics).

2.3.2.3 LABELING

a. General rules

Product labeling shall comply with the general safety standard GSO 1943/2009. This standard lists the following markings as mandatory:

- Name of the product, Trademark

- Function of the product (in Arabic if the function is not clear from the product's presentation)
- Name and address of manufacturer
- Date of production or batch number
- Durability information (PAO or Best before date)
- Weight/volume
- Country of origin
- Ingredients list (INCI)
- Instructions of use and storage (in Arabic if special instruction that may have an effect on the use of the product for consumer safety)
- Any warning (in Arabic)

Note: A minimum of Arabic translation is always required, such as for the product's function, and safety warnings or special instructions for use.

b. Specific rules

Particular attention needs to be paid to some labeling rules, in order to be in conformity with the Saudi requirements. Among those we can find the following: **Medical claims:**

Medical claims are not allowed, and terms like "treatment" are generally not accepted. Any other claims relative to "regeneration of cells," or "stimulation of collagen production," should be avoided.

Pictures and illustrations: Any pictures or illustrations that are inconsistent with the prevailing social customs and values should not be used.

Country of origin The country of origin marking is mandatory on all products and its immediate packaging; the importance of this marking was reinforced in 2010 by a MoCI decree (MoCI Royal Decree No. M/5) and is applicable to every product entering the KSA, not only cosmetic products. This mandatory requirement is strictly controlled in the country of origin/supply by the inspection agent and by customs in the KSA.

It should be noted that an indication such as "Made in EU" is not accepted; the exact country of origin must be clearly indicated. The rule is also very strict as regards to dual country of origin and labeling such as "Brand of Paris" + made in China; or "designed in France, manufactured in China," which should be avoided.

Expiry date

The marking of the expiration date is not mandatory as per GSO 1943/2009,

which only requests a “best before date” or indication “Period After Opening” (PAO). However, the expiration date is required by some SASO-specific standards, and this contradictory instruction occasionally causes issues during clearance.

Perfumery products Perfumery products standard (SASO 585/2000 – perfumery products based on ethanol) is applied in addition to the general safety standard, due to the presence of alcohol in such products, because of the sensitive issue relative to alcoholic products. This standard imposes the denaturation of ethanol, and some restrictions for products containing a percentage of essential oil/fragrance compounds lower than 8%: volume shall not be more than 250ml, and must be fitted with nonremovable pumps. Furthermore, perfumery products having a percentage of essential oil/fragrance compounds lower than 8% must bear a specific warning in Arabic “for external use only.”

Products packed in ampoules or vials Cosmetic products can be packed in ampoules or vials, even if this may sometimes be considered a medical form, provided that such products bear the following instructions in Arabic and English:

→ For external use only.
→ Avoid contact with eyes.
→ Open with caution.

2.3.2.4 MARKET ACCESS

Any cosmetic product imported into the Saudi market must present a Certificate of Conformity by the manufacturer (hereafter referred to as CoC) during customs clearance. This certificate is requested by law through the MoCI Decree 6386 as well as per the instructions published by SFDA.

a. Certification process

The SFDA regulations that outline the conformity assessment procedures demand that every shipment of cosmetic and perfumery products needs a CoC, issued by an approved inspection company, for each customs entry. The CoC needs to be issued prior to shipment, following a full evaluation of conformity against Saudi Standards and SFDA requirements. Each CoC is valid for one shipment only, and bears all reference specific to this particular shipment (such

as final invoice reference).

In order to perform certification of the country of origin, since 2011 the SFDA has officially subcontracted the evaluation of conformity and the related Certification to approved inspection bodies.

The SFDA requirements, and consequently the inspection bodies' scope of work, are that each shipment should be tested and inspected against the sanctioned standards. The Certificate issued by the inspection bodies should thereafter be presented by the importer to the local SFDA agent and Customs official at the port of entry, in order to ensure that the regulations are fully respected for any cosmetic or perfumery products entering the Kingdom.

It should be noted that the appointed inspection and certification bodies only certify cosmetic products, and not the other products' categories (herbal, health products, and drugs).

b. Conformity assessment

The first step of the certification process in the country of origin/supply, by the inspection agents, is the preclassification of the product. In certain borderline cases, manufacturers can be asked to refer directly to SFDA to obtain a written confirmation of their classification of the relevant product. Once the product is clearly identified as a cosmetic product, it will be assessed as per the sanctioned standards and SFDA requirements. This assessment is done through a documentary review, product testing, and inspection.

A nonmandatory registration system can be implemented by the inspection bodies in order to avoid testing of each shipment.

Once the document review is fulfilled and the products are found compliant, the products are physically inspected prior to shipment, in order to verify the physical integrity of the shipment against the shipping documents as well a verification of the marking of the individual products.

c. Key issues

At the points of entry, a full review of the conformity of the products can happen and samples can be randomly drawn for shipments holding a Certificate of Conformity, to ensure product and certification are correct (if a shipment of cosmetics arrives without a CoC, samples will automatically be drawn for testing).

When this situation occurs, it can happen that the local laboratories do not follow the SFDA-sanctioned safety standard and the local tests are done as per other SASO standards. The risks with such a local test is that a product may fail due to a nonsafety-related test requirement such as fatty matter for a skin cream. It is therefore recommended that a risk analysis be performed as per the specific SASO standards for specifications and labeling requirements, even if these are not officially sanctioned by the ruling authority.

ACHIEVING GLOBAL MARKET ACCESS-FOCUS ON CHINA AUTHOR

Mr. Zhongrui Li (Mr. Ray Li), Toxicological Risk Assessor,
Intertek ABSTRACT

The purpose of this chapter is to give a brief overview of the cosmetic legislation and regulatory status for importers who are interested in supplying their cosmetic products to the Chinese market. The difference and similarity between EU and Chinese regulations are summarized. Cosmetic legislation, definitions, the registration process, and new ingredient requirements are also discussed to help the reader understand how to enter the marketplace in Mainland China.

TABLE OF CONTENTS

2.3.3.1 Category of cosmetics in China: special use and nonspecial use cosmetic
2.3.3.2 Oral products requirements
2.3.3.3 Document and testing requirements during product registration
2.3.3.4 Animal testing requirements in China
2.3.3.5 Safety assessment for ingredients and finish products
2.3.3.6 Comparison of EU and China regulation requirements
2.3.3.7 Existing and new cosmetic ingredients in China

2.3.3.1 CATEGORY OF COSMETICS IN CHINA: SPECIAL USE AND NONSPECIAL USE COSMETIC

Cosmetic regulation in China is based on Regulations Concerning the Hygiene Supervision over Cosmetics (1990). “Cosmetic products” are defined as those daily-used chemical products (substance and mixture) applied on the surface of any part of the human body (such as skin, hair, nails, oral, and lips) by way of

smearing, spraying, or other similar methods to keep the body clean; to get rid of undesirable smell; to protect the skin; to make up the face, and to increase appearance and beauty. The definition is similar to that of the EU Cosmetic Directive 76/768/EEC and includes prohibited and restricted substances that are listed in the EU Hygienic Standard for Cosmetics (2007). The main difference between the EU and Chinese regulations is that cosmetic products are divided and managed in two categories: “special use” and “nonspecial use” products. Nonspecial-use cosmetics include hair care, nail care, skin care, perfumes, and makeup. Special-use products include hair growth, hair dye, hair perm, hair removal, breast shaping, fitness, deodorizing, spots removal, and sun block.

2.3.3.2 ORAL PRODUCTS REQUIREMENTS

Oral care products are not listed in either of the two categories, and instead are regulated according to other separate national standards (e.g., GB 8372-2008 gives specified requirements for toothpaste). Furthermore, there are guidelines, national standards, and industry standards on cosmetic products that present specific requirements. These include, but are not limited to, testing methods, labeling, and registration. Consequently, compliance with the legal requirements is made difficult to understand for importers or distributors foreign to China. The authorities have noticed that and now are discussing the matter with industry; it is very likely that oral products will be treated as “cosmetic” and regulated by China FDA.

2.3.3.3 DOCUMENT AND TESTING REQUIREMENTS DURING PRODUCT REGISTRATION

For imported cosmetic products, except oral care products, and unlike the trend in the EU and U.S., registration and animal testing are required by China’s State Food & Drug Administration (CFDA) before marketing. Such testing can take several months or more to perform before registration is possible. The nonspecial-use cosmetics do not require registration, but notice should be provided to provincial authorities if the products were manufactured by domestic companies, including internal brands that have manufactured products in mainland China. The Registration Documents are listed in the Table 1. The application form and all other documents should be written in simplified Chinese and the original language of the technical document should also be submitted to

CFDA together with its translation.

Table 1: China FDA required registration documents for cosmetics

Nonspecial-use cosmetics	Special-use cosmetics
Application form for imported cosmetics (nonspecial use)	Application form of imported cosmetics (special use)
Product formula—INCI name in both English and Chinese	Product formula—INCI name in both English and Chinese
Quality standard of product (specification)	For products with the function of slimming, breast care, and hair growth, documents should provide the effective ingredient based on scientific data and a brief introduction and sketch of production process.
Testing report of inspection institute accredited by Ministry of Health (MOH) and relative documents	Brief description of manufacture technology and procedure chart
Original package (including label) or package (including label) designed for the Chinese Market	Quality standard of product (specification)
Certification documents of sale permission for the registered product in country of origin (region) or manufacturing country (region)-free sale certification	If products contain ingredients that endanger health, documents should provide the related safety assessment data (test report for concerned impurities).
If products contain ingredients that endanger health, documents should provide the related safety assessment data (test report for concerned impurities)	Testing report of inspection institute accredited by Ministry of Health (MOH) and relative documents
“BSE” certificate (prepared by responsible unit of China)	Original package (including labeling) or package (including labeling) designed for the Chinese market and instruction for use in Chinese
Business license copy of responsible unit in China	Certification documents of sale permission for the registered product in country of origin (region) or manufacturing country (region)-free sale certification
Authorization letter—it will be needed if the unit responsible is to apply for registration	“BSE” certificate (prepared by responsible unit of China)
Consigned manufacturing agreement, GMP, or ISO certificate	Business license copy of responsible unit in China

Certificate of an agency issued by the unit responsible if needed	Authorization letter—it will be needed if the unit responsible is to apply for registration
Other documents that may be helpful for the record	Consigned manufacturing agreement, GMP or ISO certificate
Unopened samples	Certificate of an agency issued by the unit responsible if needed
	Other documents that may be helpful for the record
	Unopened samples

2.3.3.4 ANIMAL TESTING REQUIREMENTS IN CHINA

Animal testing for finished cosmetic products is a mandatory requirement and should be conducted by Ministry of Health (MOH) accredited laboratories in China. Rats, rabbits, and guinea pigs are normally used under finished product registration. Alternative methods are normally not accepted by CFDA even if they have been validated by OECD or other international bodies; a good example is the Guinea Pig Maximum Test (GPMT), which has been prohibited in EU. Instead, the Local Lymph Node Assay (LLNA) is recommended in order to comply with the 3R principle (Replace, Refine, and Reduce) for investigating skin sensitization potential, but at the moment China FDA only accepts the GPMT method. As a consequence, all cosmetic products that have not been tested on animals are excluded from the Chinese cosmetic market. Under pressure of international animal rights organizations and the cosmetic industry, the CFDA finally changed its attitude and approved the first *in vitro* method of 3T3 Neutral Red Uptake Phototoxicity Test in February 2012. However, a CFDA prohibition of animal testing is currently thought to be a long way off.

In the European Union, all animal testing has been banned for finished products, as well as ingredients, as of March 2013, but it is clearly mentioned that the ban is only applicable to those animal tests designed for *this regulation* in article 18 of EU cosmetic regulation EC 1223/2009. Therefore, exemption conditions exist for those tests designed to fulfill other countries' legal requirements (such as China's); the relevant data should be documented in a Product Information File (PIF) and made as transparent as possible. The authorities may not consider these animal tests to be in violation of EU cosmetic regulation.

2.3.3.5 SAFETY ASSESSMENT FOR INGREDIENTS AND FINISH PRODUCTS

A toxicological risk assessment (cosmetic safety assessment) is required in China, but this report mainly focuses on identifying prohibited substances or toxic impurities in the ingredients. For example, phenol is a common impurity in phenoxyethanol, and a testing report of phenol would normally be provided either for phenoxyethanol itself or a finished cosmetic product. Other routine test substances such as Dioxane, Methanol, Acrylamide, and N-nitrosodiethanolamine (NDELA) and their safety levels (Margin of Safety) should be calculated to demonstrate their safety if trace levels are present in the finished formulation. This is different from the EU cosmetic Regulation EC 1223/2009, which emphasizes the toxicity of intentionally added ingredients rather than the impurities. Comparable EU and China regulation requirements are summarized in Table 2.

2.3.3.6 COMPARISON OF EU AND CHINA REGULATION REQUIREMENTS

Table 2 comparison of EU and China regulation requirements

Requirement	**EU cosmetic regulation/directive**	**China legislation**
Category	Leave-on and rinse-off products	Special and nonspecial-use products
Oral products	Cosmetics	National standards
Animal testing	Banned	Mandatory
In vitro test methods	Accepted	3T3 Neutral Red Uptake Phototoxicity Test only
Notification	Yes	Yes, but for domestic manufacturers' nonspecial-use products
Registration	No	Yes, all imported cosmetics and domestic manufacturers' special-use products
Duration of notification or registration	Minimum	Notification is minimum but take several months, possibly years, for registration.
Claim of effects	Yes, document evidences in the Product Information File	Yes, reviewed by committee during registration

Testing report(s) for high-risk impurities	Not mandatory	Yes
Hygienic testing report(s)	Not mandatory	Yes
Testing samples	Not mandatory	Yes, for animal and clinical testing
Language	English and member-state official language	Simple Chinese
Organic cosmetic	Not regulated	Prohibited
Labeling	**26 allergen**	Ingredient INCI Chinese name in the label
Infant or child products	No specific requirements	Yes
Existing cosmetic ingredient	No	Yes, 3667 in three batches
New cosmetic ingredient registration	No	Must be approved before use
Nanomaterials	Notify authorities and provide safety data	Not specified, not recommended in infant or child products

Any claims of performance effect(s) are reviewed by the CFDA committee, and substantiation of these claims, such as clinical research reports for the ingredients or products themselves, shall accompany the submitted dossier. Cosmetic products intended for pregnant women and mothers during lactation are not accepted by CFDA as they cannot be justified or assessed for potential risk.

The principle of “organic cosmetics” is not recognized in China according to GB/T 19630 Organic Products, the authority AQSIQ (General Administration of Quality Supervision, Inspection and Quarantine of the People’s Republic of China). Products containing 95% or above “organic ingredient” may use the “organic” mark after the official certification process. Third party “organic” certifications are not accepted and cosmetic brands are basically prohibited from advertising their products as “organic” in mainland China.

This approach is similar to that used for “cosmeceuticals,” which is also not a recognized term. If a product has drug-like properties, it must meet the requirements for drugs as defined in the Drug Control Law of the Peoples Republic of China.

Cosmetic labeling should comply with GB5296.3-2008, and normally the approach that industry takes is to design a “patch” in Chinese and then paste it onto the original label and package. However, warning statements will not be covered by this patch. The CFDA committee obligation is to check the claim(s) on the patch but not to check the original language or the company’s official websites. Importers or suppliers to the Chinese market therefore simply need to design this “patch” rather than modify their products’ claim(s) in the original market.

To protect consumers against allergic contact dermatitis in the EU, the seventh amendment to the cosmetic directive required the listing of any one of 26 allergen names on the packaging should the concentration exceed 0.01% for rinse-off products and 0.001% for leave-on products. No such labeling is required in China. The unique requirement for labeling is that ingredients be listed by their Chinese INCI names, and if a Chinese INCI name does not exist for an ingredient, importers must apply for one. The Chinese INCI name can be identified in the Catalogue of International Cosmetic Ingredients published by the Ministry of Health (MOH).

“Nanomaterial” in cosmetics has been a hot topic in recent years, understandably so as they often provide unique and fascinating properties for products. Unique or not, the safety of these materials requires further investigation. Elsewhere in this text we cover the growing and complex field of the characterization of nanomaterials. While notification is required for products containing nanomaterials according to EU Cosmetic Regulation EC 1223/2009, the Chinese CFDA has not yet given any official opinion on use or labeling—although use of nanomaterials is not encouraged in products intended for infant or child cosmetics.

A new guide for products used on infants and children was published on October 12, 2012. One important requirement is that these types of cosmetic products should minimize the total number of ingredients relative to classes of colors, fragrances, and preservatives. It also requires proof of need for their inclusion.

2.3.3.7 EXISTING AND NEW COSMETIC INGREDIENTS IN CHINA

Existing and new cosmetic ingredients are defined in the Guidelines for the Registration and Evaluation of New Cosmetic Ingredients (2011). A new

ingredient is defined as any ingredient that is used in cosmetics for the first time in China. Basically, a “new ingredient” can be defined as any ingredient that is currently not included in the current CFDA cosmetic ingredient list—even if it is already being used in EU or U.S. markets. China FDA has published an Inventory of Existing Cosmetic Ingredients in China (IECIC 2003 & 2011), and three additional batches of existing ingredients were released in May, July, and September 2012 containing respectively 1674, 637, and 1356 substances. The lists are not exhaustive, and CFDA experts have suggested that more lists will be released over time.

Maximum approved concentration (MAC) and/or maximum used concentration in approved cosmetic products (MUCAP) are available for each ingredient. In these, if MUCAP limits are exceeded then evidence will be required to prove the safety of the finished cosmetic product during use. New ingredient registration requiring exhausted toxicity and safety data and process is extremely time consuming and expensive. CFDA took over the regulation of cosmetics from the Ministry of Health (MoH) in 2008, and since then only three new cosmetic ingredients have been approved for use. Therefore, industry has no choice but to design formulations based on the currently existing list; otherwise companies may have to wait for prolonged periods of time—sometimes years—to gain authorization to market cosmetic products containing “new” ingredient(s).

For all EU and U.S. cosmetic companies, tolerance and patience with the complex registration process are, regrettably, key factors needed to enter this huge and important market.

NANOMATERIALS IN COSMETICS: REGULATORY AND SAFETY CONSIDERATIONS

Jeffrey W. Card and Tomas Jonaitis

ABSTRACT

Nanomaterials are present as ingredients in numerous types of cosmetic products that are marketed worldwide. Regulatory and safety evaluations of nanomaterials and nanomaterial-containing cosmetic products continue to evolve with the accumulation of knowledge on the physicochemical and toxicological properties of particles at the nanoscale. This chapter provides an overview of the current state of regulation of nanomaterial-containing cosmetic products in Europe, the United States (U.S.), and Canada. It also outlines some considerations for the design and conduct of evaluations of nanomaterial toxicity that can support cosmetic product safety.

2.3.4.1 REGULATION OF COSMETICS CONTAINING NANOMATERIALS

a. Definition of Nanomaterial

The regulation of cosmetics containing nanomaterial ingredients depends, in part, on the definition of a nanomaterial, which in and of itself varies among jurisdictions. For reference, Table 1 presents a summary of the current definition of a nanomaterial for cosmetic regulation purposes in Europe, the U.S., and Canada.

Table 1 Nanomaterial Definition in Different Jurisdictions

Jurisdiction	Definition of Nanomaterial	Reference
Europe	● "Nanomaterial" means an insoluble or biopersistant and intentionally manufactured material with one or more external dimensions, or an internal structure, on the scale from 1 to 100 nm.	**1**
United States	● FDA has not adopted a formal definition of "nanotechnology," "nanoscale," or related terms.	**2**
	● Although there are numerous definitions of "nanotechnology," the term is perhaps most commonly used to refer to the intentional manipulation, manufacture, or selection of materials that have at least one dimension in the size range of approximately 1 to 100 nanometers.	
	● While one definition for "nanotechnology," "nanoscale material," or a related term or concept may offer meaningful guidance in one context, that definition may be too narrow or broad to be of use in another.	
	Any manufactured substance is a nanomaterial if:	

Canada	● It is at or within the nanoscale in at least one external dimension, or has internal or surface structure at the nanoscale; or ● It is smaller or larger than the nanoscale in all dimensions and exhibits one or more nanoscale properties/phenomena. For the purposes of this definition: ● The term “nanoscale” means 1 to 100 nanometers, inclusive; ● The term “nanoscale properties/phenomena” means properties that are attributable to size and their effects; these properties are distinguishable from the chemical or physical properties of individual atoms, individual molecules, and bulk material; and, ● The term “manufactured” includes engineering processes and the control of matter.	**3**

b. Regulation in Europe

The European Commission was the first regulatory body to formally regulate the use of nanomaterials in cosmetics. As of July 11, 2013, cosmetic products placed on the European market must conform to the procedures and data requirements contained in Regulation (EC) No. 1223/2009 of the European Parliament and of the Council 1. As of this date, a Product Information File (PIF) for each cosmetic product marketed in Europe must be maintained by a “Responsible Person” within the Community (defined as "a legal or natural person established within the Community"). Each PIF contains a cosmetic product safety report and other pertinent information for a given cosmetic product and must be made available to regulatory authorities if requested. Moreover, the Responsible Person must notify the Commission prior to the introduction of a cosmetic product to the European market. While notification for cosmetic products that do not contain nanomaterials can be made immediately prior to placement on the market, notification for cosmetic products containing nanomaterials must be made six months prior to placement on the market 1. In the latter case, the notified information must contain the following:

1. The identification of the nanomaterial including its chemical name (IUPAC) and other descriptors
2. The specification of the nanomaterial including size of particles and

physical and chemical properties

3. An estimate of the quantity of nanomaterial contained in cosmetic products intended to be placed on the market per year
4. The toxicological profile of the nanomaterial
5. The safety data of the nanomaterial relating to the category of cosmetic product, as used in such products
6. The reasonably foreseeable exposure conditions

The Regulation does not provide specific guidance on how to address some of the items listed above (e.g., the specific types of toxicological data required), but such guidance is available from the European Commission's Scientific Committee on Consumer Safety (SCCS). Specifically, guidance is available that assists with understanding what needs to be considered when evaluating the safety of cosmetic ingredients in general 4 and when conducting physicochemical characterization, exposure assessment, hazard identification and dose response, and overall risk assessment evaluations for nanomaterials in cosmetics 5. Based on SCCS guidance, the following parameters are considered important for identification and characterization of nanomaterials in cosmetic products 5:

1. Chemical identity
2. Chemical composition and purity
3. Size and size distribution
4. Morphology
5. Surface characteristics (charge, modifications, etc.)
6. Solubility
7. Surface area
8. Catalytic activity
9. Concentration
10. Dustiness (for dry powder products)
11. Density and pore density
12. Redox potential
13. pH
14. Viscosity
15. Stability
16. Other aspects (e.g., ultraviolet absorption, light reflection)

In the event that information supplied for a given nanomaterial raises concerns about its safety, the Commission may request the SCCS to issue a formal opinion. These opinions focus on the safety of the nanomaterial for use in the

relevant categories of cosmetic products and on the reasonably foreseeable exposure conditions. Timelines have been established for the SCCS to request additional information to assist with its evaluation of a given nanomaterial, for such information to be provided, and for a final opinion to be issued, all of which is made publicly available.

Unlike in other regions, special labeling requirements have been established for nanomaterial-containing cosmetics in Europe. Specifically, all nanomaterial ingredients present in a cosmetic product marketed in Europe must be clearly indicated in the list of ingredients and be followed by the word “nano” in brackets. Moreover, the Regulation calls for the creation and maintenance of a publically available catalogue of all nanomaterials that are used in cosmetic products placed on the market. This catalogue will be made available by January 11, 2014 and will indicate categories of cosmetic products that contain nanomaterials and the reasonably foreseeable exposure conditions. In recognizing that understanding nanomaterial safety is a pragmatic process, the Commission has set a deadline of July 11, 2018 for undertaking the first review of the provisions of the Regulation that concern nanomaterials, and will propose suitable amendments to the provisions where it is deemed necessary.

c. Regulation in the United States

As outlined in a recent draft guidance document on the safety of nanomaterials in cosmetics 2, cosmetic ingredients (with the exception of color additives) and cosmetic products are not required to be notified and do not require premarket approval from the U.S. Food and Drug Administration (FDA) in order to be placed on the U.S. market. With some exceptions (e.g., color additives and ingredients that are prohibited or restricted from use by regulation), a manufacturer may use any ingredient in a cosmetic product formulation as long as the use of the ingredient does not otherwise cause the product to be adulterated or misbranded. The manufacturer is responsible for ensuring that the cosmetic product is not misbranded or adulterated, and manufacturers or distributors should have obtained all data and information needed to substantiate the safety of the product before marketing.

The safety of any cosmetic product to be marketed in the U.S. should be evaluated by assessing the physicochemical properties and relevant toxicological endpoints for each ingredient in relation to the expected exposure levels that will result from the intended use of the finished product. For cosmetic products

containing nanomaterials, the FDA recommends that safety assessments address several important factors, including the following 2:

1. Physicochemical characteristics (including size and size distribution, aggregation/agglomeration, surface chemistry, morphology, solubility, density, stability, and porosity)
2. Agglomeration and size distribution of nanomaterials under the toxicity-testing conditions that should correspond to those of a final product
3. Impurities
4. Potential product exposure levels, and the potential for agglomeration of nanoparticles in the final product
5. Dosimetry for in vitro and in vivo toxicology studies
6. In vitro and in vivo toxicological data on ingredients and their impurities, dermal penetration, irritation (skin and eye) and sensitization studies, and mutagenicity/genotoxicity studies
7. Clinical studies to test the ingredient, or finished product, in human volunteers under controlled conditions

With regard to toxicity testing for nanomaterials, FDA has indicated that manufacturers should consider modifying traditional methods by giving consideration to appropriate solvents and dosing formulations, methods to prevent agglomeration of nanoparticles, purity and stability conditions, and other variables. FDA recommends that, at a minimum, evaluations be conducted for acute toxicity, skin irritation, dermal photo-irritation, skin sensitization, mutagenicity/genotoxicity, repeat-dose toxicity (21 to 28 days), and subchronic toxicity (90 days), and take into consideration toxicokinetics and toxicodynamics with regard to different exposure routes 2.

Manufacturers of cosmetic products are encouraged to contact the FDA if they are considering using a new nanomaterial or an altered (i.e., nanoscale) version of an ingredient already on the market so that discussions can be held regarding test methods and data needed to substantiate a given product’s safety.

d. Regulation in Canada

Notification is a mandatory requirement for the sale of cosmetics in Canada. A Cosmetic Notification Form must be submitted to Health Canada within ten days of making a cosmetic product available for sale in Canada. This form provides information specific to each cosmetic product, including the address and contact information of associated companies, the purpose of the cosmetic (shampoo,

lipstick, etc.), the form of the cosmetic (gel, liquid, etc.), and a list of the ingredients and their concentrations.

Ultimately, manufacturers are responsible for ensuring that their cosmetic products meet the requirements for cosmetic products under the Canadian Food and Drugs Act and the Cosmetic Regulations. To assist manufacturers in determining whether ingredients are safe for use in cosmetics, Health Canada maintains a list of prohibited and restricted cosmetic ingredients (the “hotlist”). While there were no nanomaterials listed in the cosmetic ingredient hotlist as of late 2012, this list is not exhaustive, and Section 16 of Canada’s Food and Drugs Act permits Health Canada to restrict or prohibit any ingredient it deems unsafe.

Specific guidance is not readily available regarding the regulation of nanomaterials in cosmetics in Canada. In late 2011, Health Canada released a policy statement on its working definition of nanomaterial 3. At that time, Health Canada indicated that existing risk assessment methodologies are applicable to nanomaterials, and that guidance documents would be developed over time for nanomaterials specific to products, substances, or commodity groups. Given its authority within existing legislative and regulatory frameworks, Health Canada may request the submission of information on specific nanomaterials in cosmetics and other regulated products to assist with assessing potential risks due to exposure to nanomaterials via the use of such products. Such information may include the following (when relevant) 3:

1. Intended use, function, and purpose of the nanomaterial, and information regarding any end product in which it will be used
2. Manufacturing methods
3. Characteristics and physicochemical properties of the nanomaterial such as:
   a. composition
   b. identity
   c. purity
   d. morphology
   e. structural integrity
   f. catalytic or photo-catalytic activity
   g. particle size/size distribution
   h. electrical/mechanical/optical properties
   i. surface-to-volume ratio
   j. chemical reactivity
   k. surface area/chemistry/charge/structure/shape
   l. water solubility/dispersibility

m. agglomeration/aggregation (or other properties)
n. descriptions of the methods used to assign these determinations

4. Toxicological, eco-toxicological, metabolism, and environmental fate data that may be both generic and specific to the nanomaterial if applicable
5. Risk assessment and risk management strategies, if considered or implemented

Manufacturers and other stakeholders are encouraged to establish communication with Health Canada early in the development process for products (including cosmetics) that are, contain, or make use of nanomaterials.

On September 13, 2001, the Minister of Health confirmed the government's intention to proceed with the development of new environmental legislation for all products regulated under the Food and Drugs Act, including cosmetics, as their ingredients would no longer be exempt from the requirements of the Canadian Environmental Protection Act, 1999 (CEPA). Health Canada is in the process of developing Environmental Assessment Regulations to address the unique properties of ingredients in cosmetics and other products. However, until the new Regulations are developed, these substances are subject to notification and assessment requirements under the New Substances Notification Regulations (NSNR) of CEPA. The NSNR represent a volume-based, premanufacture/preimport notification program that requires the submission and government assessment of physical and toxicological information for nonexempt chemicals and polymers that are not listed on the Domestic Substances List (DSL). The amount of information and the studies that must be submitted to the government are described in a series of NSNR "Schedules." The specific Schedule that applies is dependent on a variety of factors including, but not limited to: the anticipated manufacture or import quantity of the notifiable substance (i.e., in kg/year); the inherent nature of the substance (e.g., chemical, polymer, or low-concern polymer); the intended use of the substance (e.g., research & development, site-limited, export-only); and whether the substance is listed on the Non-Domestic Substances List (NDSL).

Within the NSNR program, nanomaterials that are manufactured in or imported into Canada that are not listed on the DSL are considered new. Although there is no internationally recognized definition of this type of substance, for purposes of the NSNR, nanomaterials can be described generally as substances having one or more dimensions in a nanoscale range, typically between 1 and 100 nanometers. The nanoscale form of a substance on the DSL is considered a "new" substance if it has unique structures or molecular

arrangements. Substances listed on the DSL whose nanoscale forms do not have unique structures or molecular arrangements are considered existing and are not subject to the NSNR. In addition, incidentally produced or naturally occurring nanomaterials are not subject to notification.

2.3.4.2 SAFETY ASSESSMENT CONSIDERATIONS FOR NANOMATERIALS

a. Study Design Aspects

The safety of nanomaterials contained in cosmetics and other products must be supported by data generated in studies that are of high quality in terms of their design and reporting 6. While not always feasible, such studies ideally adhere to established testing guidelines, such as those published by the Organisation for Economic Cooperation and Development (OECD), and to the principles of Good Laboratory Practice. Tiered strategies have been proposed to evaluate the safety of nanomaterials wherein *in vitro* and *in vivo* screening studies are followed by pivotal *in vivo* studies and supportive mechanistic studies 7–9. While this may be an ideal scenario, the evaluation of nanomaterial toxicity is particularly challenging in Europe given the restrictions that are in place on animal testing in Europe and the fact that validated alternative methods currently available for conventional chemical substances (e.g., skin corrosion, skin irritation, mutagenicity, photomutagenicity, phototoxicity, and dermal absorption) have not been validated specifically for nanomaterials 5.

At the present time there are insufficient data on nanomaterial properties, behavior, and effects to allow for nanomaterial safety to be evaluated using a read-across approach (i.e., based on structural surrogates or categories of substances). Thus, substance-specific data (i.e., those generated with the substance of interest) are generally required to support the safety of a given nanomaterial. In cases where specific endpoints have not been evaluated with the substance of interest, information from the published literature may be useful if it is deemed to be relevant (i.e., based on a substance that is sufficiently similar in terms of physicochemical properties) and of suitable quality. In this respect, it is worth noting that published scientific articles do not always provide data that can be used for safety assessment purposes. Physicochemical characterization is a key element to nanomaterial study design and its importance is discussed further below. In addition, as for any study, those that are conducted with

nanomaterials need to consider the importance of general study design and adequate documentation of methods, materials, and results. Unfortunately, as summarized in a review of the published literature on the safety of food-related nanomaterials 10, there are many examples of peer-reviewed published articles in which it is difficult or impossible to discern simple yet critical experimental details, such as the number of animals per treatment group, the method/route of exposure, or the doses or concentrations of the substance that was tested. Thus, caution must be exercised when attempting to use publicly available information to support the safety of a particular nanomaterial.

b. Nanomaterial Characterization

Characterization of the physicochemical properties of nanomaterials is paramount to understanding their behavior in biological systems and conducting risk assessments related to potential exposure. Lack of adequate nanomaterial characterization limits the value and significance of a given study and renders it impossible to compare studies and recognize parameters that might influence toxicity. The physicochemical characteristics of a given nanomaterial may differ considerably in the “raw” versus the “tested” state and may be influenced by the solvent, test media, or biological environment that is utilized in a particular evaluation. As such, the SCCS has recommended that, unless otherwise justified, characterization of nanomaterials for use in cosmetics be undertaken under at least the following three conditions: i) in the raw form as manufactured; ii) as present in the final cosmetic formulation; and iii) as present during toxicological evaluations (in the dose formulation, cell culture, etc.) 5.

The importance of nanomaterial characterization was highlighted in a review of the published literature on the safety of food-related nanomaterials 10. Among other findings, this review identified that information on nanomaterial purity was lacking in more than half of the published articles that reported on studies of the oral toxicity of food-related nanomaterials. This seemingly simple oversight in many published articles renders the results of such nanomaterial toxicology studies difficult to interpret, and emphasizes the need for sufficient physicochemical characterization in nanomaterial toxicology studies to allow for their inclusion in risk assessments.

Toxicological properties of food-related nanomaterials is of particular importance as the cosmetic and personal care industries move increasingly towards the concept of “beauty from within” and the growing use of

nutraceuticals. Concerns of nanoparticle incorporation in organs of the body and elsewhere would appear to be very important since the size of a nanoparticle is at a level where cell penetration may be of significance. Thus, there remains much to do regarding the reliability of measuring and reporting toxicological impacts of ingested nutraceuticals.

c. Dose Metrics

Due to their large surface area per particle mass or particle volume, traditional means of expressing dose levels as mass or volume units (e.g., mg/kg body weight or mg/L) may not be appropriate for nanomaterials, particularly those that are insoluble in aqueous systems. Other metrics, such as particle number or relative surface area, may be more relevant to dose-response relationships and need to be considered when designing and evaluating the results of toxicology studies 2, 5, 7, 11. Thus, characterization of the physicochemical properties of nanomaterials should be conducted in a manner that allows for the derivation of such alternate dose metrics.

The results of a study reported by Oberdorster *et al.* 12 provide an example of the influence of dose metrics on data interpretation. When expressed in terms of equivalent mass, lung inflammation in rats was observed to be more severe (i.e., the dose-response curve was steeper) following installation of 25 nm TiO_2 nanoparticles than following installation of 250 nm TiO_2 nanoparticles. But when the dose was expressed in terms of relative surface area of the instilled nanoparticles, the dose-response curves for the two nanoparticle sizes overlapped. Thus, for particles with the same chemistry, but of different sizes, particle surface area may be a more relevant dose metric and should be considered when evaluating the results of toxicological studies. Such studies are of particular importance for nano-size TiO_2 particles in view of their wide use in sunscreen agents and other cosmetics.

d. Assay Interference

Various types of nanomaterials may interfere with assays commonly used to determine cellular or toxic effects. Numerous examples have been cited in the published literature and include interference with optical or other detector measurements, interference with colorimetric or fluorometric dyes used in cytotoxicity assays, interference with measurement of reactive oxygen species, and adsorbance to essential growth factors and nutrients in cell culture media

that leads to indirect growth inhibition and apparent cytotoxicity 13–15. Such effects may lead to false positive or false negative readouts, examples of which are presented in Table 2.

Table 2 Examples of Assay Interference by Nanomaterials

Assay	Interference	Altered Readout	Nanomaterial
MTT (cell viability)	Adsorption of substrate	Decreased indication of cell viability (false positive)	Carbon nanoparticles
LDH (cell viability)	Inhibit LDH activity	Decreased indication of cytotoxicity (false negative)	Trace metal-containing nanoparticles
ELISAs (inflammatory response)	Adsorption of cytokines	Decreased indication of inflammation (false negative)	Metal oxide nanoparticles

Abbreviation: ELISA, enzyme-linked immunosorbent assay; LDH, lactate dehydrogenase, MTT, (3-[4,5-dimethylthiazol-2-yl]-2,5 diphenyl tetrazolium bromide).

It is of particular interest to note that the MTT cell viability assay has been reported to be affected by some nanomaterials. This is one of the recommended assays for assessing cell viability in OECD test guideline number 431 (*In Vitro* Skin Corrosion: Human Skin Model Test) 16. As such, the possibility of false positives from this assay, and others, needs to be carefully considered when evaluating skin corrosion and other toxicological endpoints for nanomaterials.

CONCLUSION

Regulatory and safety evaluations of nanomaterials and cosmetic products that contain nanomaterials are evolving processes. Considering that nanomaterials can, and have the potential, to possess properties quite unlike their macroscopic counterparts, the unique physicochemical properties of nanomaterials present many difficulties with respect to characterization and toxicity testing. These differences contribute to the challenges associated with conducting risk assessments for cosmetic products containing nanomaterial ingredients. The continued accumulation of knowledge on nanomaterial properties and safety and the development of additional validated methods for evaluating these aspects will assist regulatory communities around the world in ensuring that cosmetic

products containing nanomaterial ingredients are safe for use by consumers worldwide.

ABSTRACT

The skin is the organ that forms the border between the organism and the environment. Skin prevents dehydration, stops the penetration of noxious foreign materials and microorganisms, cushions against mechanical shock, helps to maintain a constant body temperature, and transduces incoming stimuli. In order to perform these functions, skin must be maintained in good condition, an important objective for cosmetic formulators. For cosmetic and personal care scientists, whether they are concerned with the improvement of the skin by pharmacology or cosmeceuticals, with the prevention or repair of damage, an understanding of skin structure and function is essential. As such, this section has a primary focus upon these issues.

Further, the impact of light on skin and on skin aging has become so important in cosmetics that it too requires a complete discussion. This chapter is carefully and thoroughly designed to provide a basic knowledge of skin structure and function, thereby forming a sound foundation for the reader to understand key issues and provide stimulation towards the generation of new ideas and novel approaches for new ingredients, addressing the global quest for advanced cosmetic and personal care products.

PART 3.1.1 SKIN MORPHOLOGY

The skin is divided into three layers: the epidermis, the dermis, and the subcutaneous tissue. The epidermis is the outermost layer of the skin and consists of a stratified squamous epithelium. Its thickness varies, depending on location, and varies from 0.05 mm to 1.5 mm. The epidermis is made up primarily of keratinocytes, whose basic function is to produce a filamentous protein, keratin, to serve as a protective barrier in combination with various lipid components. These cells also produce several other proteins, for example, cytokines, which play a role in the cutaneous inflammatory response. Separated from the epidermis by the basement membrane, the dermis is composed primarily of the so-called ground substance, which includes glycosaminoglycans (GAGs) and the structural protein collagen. Its thickness also varies with location from 0.3 mm to 3.0 mm. The dermis is divided into two layers: the papillary layer, which interdigitates with the epidermal rete ridges, and the reticular layer, which extends to the subcutaneous tissue. This deepest layer of the skin, also known as the subcutis or hypodermis, is composed primarily of lipocytes with fibrous septae providing structure and support (Fig. 1.1).

(Reprinted from Harry's Cosmeticology 8th Ed.2000)

PART 3.1.2 EPIDERMIS AND THE KERATINIZING SYSTEM

The epidermis measures approximately 100 micrometers in thickness and consists of a number of layers: the innermost basal layer (*stratum basale* or *stratum germinativum*) which attaches to the basement membrane at the dermoepidermal junction, the prickle layer (*stratum spinosum*), the granular layer (*stratum granulosum*), the clear layer (*stratum lucidum*) and the horny layer (*stratum corneum*). Together the basal layer and the prickle layer comprise the Malpighian layer. The viable epidermis (the basal, prickle, and granular layers) consists of about 10 biologically active keratinocytes. The stratum corneum is located on top of the viable epidermis. The stratification into the layers is the result of changes in the keratinocytes as they mature and move outward from the basal layer, in which they are continuously formed by the mitosis of self-renewing progenitor cells, which lose their nuclei and are shed from the skin surface (Fig. 1.2).

Figure 1.2. Conversion of individual basal keratinocytes into the flat cells of the stratum corneum (*Reprinted from Harry's Cosmeticology 8th Ed.2000*)

The replacement time for the whole epidermis is about 42 days and it is about 14 days for the *stratum corneum*. While the process of keratinization remains incompletely understood, in normal skin the desquamation of keratinocytes is in equilibrium with the generation of keratinocytes by mitosis of the proliferating cells. The importance of this equilibrium is best understood by studying examples of those skin diseases with abnormal keratinization. Abnormally rapid transformation of basal cells into horny cells of the *stratum corneum* occurs in psoriasis. *Ichthyosis vulgaris*, on the other hand, is a genetic disorder that results from abnormal retention of keratinocytes.

Three other cell types are present in the epidermis: melanocytes, the dendritic pigment-synthesizing cells; Langerhans cells, which are colorless and dendritic in form and perform functions related to immunology; and Merkel cells, which are concerned with sensation. The melanocytes and the Merkel cells are confined mainly to the basal layer, while the Langerhans cells are distributed in the basal, spinous, and granular layers.

a. DermoEpidermal Junction

The basement membrane zone forms the junction between the epidermis and the dermis. Under the electron microscope, it is seen to be composed of four components, listed from the outermost layer: the plasma membrane of the basal keratinocytes, the clear lamina lucida, the electron-dense basal lamina, and the dermal fibrils and bundles of fine filaments [1]. Some details of the components of this junction are provided in a later segment of this section.

b. Stratum Basale

The basal layer is a continuous layer of cells that gives rise to all the keratinocytes through mitotic activity. It is usually described as being one cell thick, but in thick normal or in pathological epidermis it appears that mitosis may not only be confined to cells in contact with the basement membrane. A portion of the basal cells is proliferative; these are the cells that differentiate and move up through the epidermis, eventually to become the components of the *stratum corneum* (essentially “dead” cells that are anuclear) and later desquamate at the top of the skin.

Cells of the *stratum basale* are cuboidal and have a basophilic cytoplasm and dark-staining, elongated nuclei; under the electron microscope their cytoplasm reveals many ribosomes, mitochondria, and in some cases smooth membranes. In addition, they contain numerous fine tonofilaments, about five nm in diameter, which form the developing cytoskeleton. The basal cells also often contain melanin, transferred from adjacent melanocytes. Intercellular bridges, or desmosomes, connect basal cells with one another and with the overlying squamous cells. Modified desmosomes, or hemidesmosomes, connect the basal cells to the underlying basement membrane zone.

c. Stratum Spinosum

The *stratum spinosum* is so called because the cells are given a spiny appearance by the numerous desmosomes. These desmosomes, or specialized attachment

plates for the cellular tonofilaments, correlate with the intercellular bridges between keratinocytes. The glycocalyx is the intercellular cement between keratinocytes and is composed of glycoproteins. In the upper region of the stratum spinosum, lamellar granules, also known as keratinosomes or Ödland bodies, make their appearance. These are ovoid bodies about 100–500 nm long. In the *stratum granulosum* they ultimately migrate toward the periphery of the cell and are discharged into the intercellular spaces. Their appearance there correlates with the degradation of keratinocytes. Their lipid contents act to establish a barrier to water loss and may participate in *stratum corneum* cellular cohesion. Water loss, as is well known, is a critical phenomenon that is measured in the development of new skin care products and relates to some aspects of skin aging.

d. Stratum Granulosum

The thickness of the granular cell layer is usually proportional to the thickness of the *stratum corneum*. It may be only one cell layer thick in thin skin and up to ten layers in the thicker skin found on the palms and soles of the feet. The cells contain basophilic granules of a material called keratohyalin, a material thought to be responsible for keratin filament aggregation. The “hard” keratins of hair and nail lack these keratohyalin granules.

e. Stratum Lucidum

The *stratum lucidum*, not seen in most formalin-fixed sections, is located at the deepest portion of the *stratum corneum*. It can be recognized only in palmar and plantar skin.

f. Stratum Corneum

In the *stratum corneum* the keratinocytes have lost their nuclei and virtually all of their cytoplasmic organelles and contents, including the keratohyalin granules. This layer of cells is about 10–15 cells thick (approximately 10 micrometers) and is located on top of the viable epidermis. The corneal cell layer stains eosinophilic with the hematoxylin and eosin stain due to the absence of basophilic nuclei. The cells are flattened and completely filled with keratin. The keratin is in the form of bundles of filaments embedded in an opaque interfilamentous material. They align into disulfide crosslinked macrofibers under the influence of filaggrin, the protein component of the keratohyalin granule responsible for keratin filament aggregation [2].

The structure of the *stratum corneum* has been compared to that of a brick wall, with the corneocytes as bricks and the intercellular lipids as mortar [3]. Horny cells are continuously shed from the skin surface. *Stratum corneum* lipids have been characterized and consist of phospholipids, glucosylceramides, cholesterol, cholesterol sulfate, cholesterol esters, ceramides, and fatty acids [4]. The makeup of lipids suggests that hydrophilic lipids are excluded from the *stratum corneum* to provide a hydrophobic surface on the skin.

PART 3.1.3 TERMINAL DIFFERENTIATION

Terminal differentiation describes the change of the cuboidal keratinocytes (on the basement membrane) to the flat cellular remnants that are shed from the skin surface. The progressive changes of keratinocytes as illustrated in Figure 1.2 are accompanied by biochemical changes, formation of keratins, formation and hydrolytic changes in lipids, loss of water, and crosslinking of cell envelopes. The formation of keratins proceeds from the intermediate filaments present in keratinocytes. Intermediate filaments of more than 50 types are synthesized in human tissues. In skin, two types (I and II) are specifically expressed in epithelial cells. In this classification, acidic keratins (cytokeratins K9–K20) are identified as type I, while the basic keratins (cytokeratins K1–K8) are classified as type II. In skin, the keratins are customarily dimers of one type I and one type II. The fundamental structure of the intermediate filaments includes coil-coil alpha-helical segments bonded to each other by nonhelical linker segments. Both ends of the rod-shaped filament are terminated by peptides. The exact modus of attachment of these filaments to each other to form the keratins within the keratinocytes is still under investigation. As noted, epithelial cytoskeletal filaments generally belong to one of two keratin (acidic or neutral-basic) groups ranging in molecular weight from about 40 to 70 kDa. Fillaggrin has been identified as one of the keratohyalin proteins forms in differentiating keratinocytes. Filaggrin is involved in the aggregation of keratin filaments to form the keratins found in mature keratinocytes or corneal cells. After filaggrin has served its function as a matrix between intermediate filaments, it is hydrolyzed enzymatically to create various free amino acids that form part of the natural moisturizing factor (NMF).

The hydrolytic changes of the epidermal lipids are also controlled by keratinocytes, which discharge lipids into the intercellular space after forming the lamellar granules. These lipids are distinctly different from the sebaceous

lipids secreted by the sebaceous glands. In the process of terminal differentiation, which requires about three to four weeks, the basal keratinocyte generates a remarkable set of complex lipids (e.g., ceramides). During the cells' passage outward, these lipids are modified (become more hydrophobic) to contribute to the biphasic structure commonly called *stratum corneum*.

During their ascent to the skin surface, the keratinocytes shrink, primarily through loss of water. The fate of this water is not known, but one may safely assume that it becomes part of the evaporating water generally described as trans-epidermal water loss. The loss of water during the maturation of keratinocytes is an important phenomenon that must be considered in studies of skin moisture levels (Fig. 1.3) and the impact of ingredients used in cosmetic and personal care products to improve the skin's ability to retain its moisture. The level of water in the basal layer is about that found in internal tissues, that is, about 80–85%. The water level drops stepwise to about 35% at the border between the *stratum granulosum* and the *stratum corneum*. The water level in the topmost layers of the skin is variable and is under the control of the environment and the evaporative flux from lower skin layers.

Figure 1.3. Water concentration profile in epidermal layers [SC—stratum corneum; GR—stratum granulosum; SP—stratum spinosum; B—basal layer (stratum germinativum. (*Reprinted from Harry's Cosmeticology 8th Ed.2000*)

Finally, the proteins in the cell membranes of the maturing keratinocytes undergo drastic changes due to crosslinking. This provides the terminally differentiated corneal cell with a rigid cell envelope that is chemically resistant and acts as a protective coating. The most important enzymes that play a role in this process are transglutaminases that catalyze epsilon- (gamma-glutamyl) lysine crosslinking. Involucrin is the primary cytoplasmic precursor to the protein making up the cell envelope. Other crosslinked proteins are present and have been identified—for example, loricrin.

Biologists have further identified some layers within the *stratum corneum*.

The desquamating layer at the surface is frequently called the *stratum corneum* disjunction, while the layer below it is known as *stratum corneum* conjunction. To complete this highly simplified discussion of the skin, it is important to note that the latter is frequently identified as viable epidermis. Cells from this layer can be cultured and are commonly used to study the release of cytokines and the like as well as the impact of drugs and/or cosmetic ingredients. In contrast, the nonviable epidermis includes only the dead cells of the *stratum corneum*.

Before leaving the life history of the epidermis, the process of differentiation should be considered as proceeding from the inside to the exterior. The outward movement of biological debris, water, and lipids directly opposes human efforts to drive ingredients/drugs into and through the skin unless special efforts are made to create molecules that are shaped and manipulated to permeate.

PART 3.1.4 PIGMENTARY SYSTEM OF THE SKIN

Melanocytes are dendritic cells that produce and secrete melanosomes, which contain melanin. Melanin is the major determinant of skin color. The number of melanocytes in the epidermis is the same—regardless of skin color; it is rather the number and size of melanosomes produced that determine the color of one's skin. Melanosomes in dark skin are nonaggregated, whereas they are smaller and form membrane-bound complexes in light skin. Melanocytes are derived from the neural crest in the embryo and are seen in the basal layer of the epidermis by the eighth week of gestation. They differ from the other cells of the *stratum basale* by the possession of dendritic processes, by which they transfer pigment to a group of keratinocytes; the whole forming the "epidermal melanin unit" [5]. Typically each melanocyte is associated with about 36–40 keratinocytes in the human epidermis. Melanocytes have no desmosomes and thus, when stained with hematoxylin and eosin, appear to have a halo due to the separation from adjacent keratinocytes. The concentration of melanocytes, though, does vary in different areas of the skin, with the highest concentration on the face and the male genitalia and the lowest concentration on the trunk.

The characteristic feature of melanocytes is a special cytoplasmic organelle known as a melanosome in which the melanin is formed by the action of the enzyme tyrosinase. The melanosomes arise as spherical, membrane-bound vesicles in the zone of the Golgi apparatus and eventually appear as densely pigmented granules [6].

Melanins consist of two kinds of quinoid polymers: pheomelanins and

eumelanins. Pheomelanins are yellow or red in color, and eumelanins produce the brown or black color. Both are formed by the same initial steps, which involve oxidation of tyrosine to 3,4-dihydroxyphenylalanine (DOPA) and its dehydrogenation to DOPAquinone. The formation of eumelanins then involves several further steps to produce indole-5,6-quinone, which polymerizes and becomes linked to protein. It is now believed that eumelanin is not a homopolymer composed solely of indole-5,6-quinone units but rather a poikilopolymer that includes several intermediates. Pheomelanins are formed by a different route. The DOPAquinone interacts with cysteine to form 5-S- and 2-S-cysteinyldopa, and these isomers are further oxidized to a series of intermediates that then polymerize [7].

The formation of melanin depends on the generation of free radical species. The biochemical pathways leading to the formation of melanin pigments *in vivo* were described by Raper [8] and more recently by Prota [9, 10]. This information can be found in most textbooks of biochemistry and is not repeated here. Once formed, melanin has been identified as a (stable?) free radical that can react with superoxide.

The significance of melanin as a purported photoprotectant and the response of skin to ultraviolet (UV) irradiation are critically important to skin appearance and health, especially with regard to sun exposure.

PART 3.1.5 LANGERHANS CELLS AND DENDRITIC CELLS

The skin provides the first line of immune surveillance against biologic pathogens and chemical irritants through a network of sophisticated and specialized antigen-presenting cells. These include Langerhans cells (LCs) in the epidermis and several distinct types of interstitial dendritic cells (DCs) in the dermis. LCs and DCs are the sentinels that recognize certain antigens as well as recognizing tumors. For example, they recognize foreign environmental antigens such as irritating chemicals (thereby inducing contact hypersensitivity), microorganisms (thus protecting through antimicrobial immunity). They also recognize tumors (providing antitumor immunity) and allogeneic markers (causing skin graft rejection).

The extended dendrites of these unique cells form a network within the epidermis and in the dermis they create an immunologic barrier primed to recognize, capture, and process pathogens and foreign antigens for presentation to naïve and memory T-lymphocytes, thereby initiating and then modulating the

subsequent immune response. Furthermore, the LCs and DCs play a significant role in inducing peripheral immunologic tolerance to innocuous environmental proteins and to self-antigens, thus helping to prevent autoimmune disease.

LCs are the epidermal resident dendritic cell population. They make up about 3–5% of the suprabasal, *stratum spinosum* layer of the epidermis [11] including the mucosal epithelia lining the ocular oral and vaginal surfaces [12]. LCs are scattered without desmosomal connections between keratinocytes. In light microscopic sections, LCs cannot be detected by routine histologic staining, but only by staining with gold chloride (for human LCs).

LCs are characteristically stellate with extensive dendritic fibers stretching in all directions, forming a network within the *stratum spinosum* layer. When viewed by phase contrast microscopy, the DCs extend delicate flower-like projections that bend, retract, and reextend. This shape and motility enable them to accomplish their function of capturing antigens and of selecting and processing the antigens for specific T-cells [13]. By means of high-powered electron microscopy, LCs have been shown to be a folded nucleus and are identified by their distinctive, intracytoplasmic *Birbeck granules* that (when mature) are rod shaped with a vacuole at one end, resembling a tennis racquet. Antigen capture seems to be a consequence of binding to langerin, a calcium-dependent lectin that specifically binds mannose as well as other sugars and is found only in LCs and some dermal DCs [14]. This binding actually induces formation of Birbeck granules and then routes the antigen into the Birbeck granules for further processing.

Langerin is a recognition receptor for carbohydrates on the surfaces of pathogens that routes antigens to different cellular compartments involved in antigen presentation in order to promote recognition by different specific T-cells [15].

In addition to LCs, the skin has at least four other subclasses of DCs in the dermis. The characterization of these DCs is quite complex because DCs can arise from several types of progenitor cells, and different functional phenotypes of DCs can be generated from the same precursor cell (as determined by function required, generating a sequential encounter with specific cytokines). Furthermore, as the LCs and DCs encounter a foreign antigen and migrate, they mature, and their surface markers as well as their functional interactions change. Thus, the steady-state population is different from the inflammatory response populations.

Langerhans cell function is impaired by UVB radiation, resulting in a decrease in the antigen-presenting capacity and in the production of cytokines. This UV suppression leads not only to adverse consequences by impairing endogenous antimicrobial activity and tumor recognition and suppression, but also to possible advantageous therapeutic treatments for skin allergy and inflammatory disease.

PART 3.1.6 DERMIS

The dermis is a tough and resilient tissue that cushions the body against mechanical injury and provides nutrients to the epidermis and cutaneous appendages [16]. It consists of an association of protein fibers within an amorphous ground substance containing glycosaminoglycans (GAGs), previously known as mucopolysaccharides. There are few cells in this matrix; most of them are fibroblasts, which secrete the dermal constituents. Fibroblasts are derived from the mesenchyme. The mast cell, also of mesenchymal origin, houses granules that contain heparin, histamine, and other active substances. The mast cell is an active participant in skin inflammation and irritation, as well as in several other skin disorders. The dermis also houses blood, contains lymphatic and nervous systems, and surrounds the invaginated epidermal appendages. The GAGs in the dermis can hold copious amounts of water and tend to surround the other constitutents of the matrix. Together with the fibrous portion of the matrix, these substances account for the skin's flexibility and resistance to deformation.

a. Collagen

The major fibrous constituent of the dermis, accounting for 75% of the dry weight and 18–30% of the volume, is collagen [17]. Under the light microscope, collagen fibers appear as eosinophilic branching wavy bands. Collagen fibers are loosely arranged in the papillary dermis and are tightly bundled in the reticular dermis. Pilosebaceous units, eccrine glands, and apocrine and dermal blood vessels are surrounded by a thin meshwork of collagen. Collagen fibers display characteristic cross-striations with a periodicity of 60–70 nm. Collagen is rich in the amino acids hydroxyproline, hydroxylysine, and glycine. The fibroblasts produce a precursor known as procollagen, which includes 300–400 additional amino acids in each of its chains; these extensions are removed after secretion, which results in the conversion to the collagen molecule. Collagen fibrils form by the association of collagen molecules. Vitamin C and copper are two of

several cofactors required in the biosynthesis of collagen. Collagen production is a dynamic process that involves continual synthesis by fibroblasts and degradation by collagenases.

b. Elastin and Reticulin

Elastic fibers make up only 4% of the dry weight and 1% of the volume of the dermis. They are delicate, straight, freely branching fibers that prove very resilient. These fibers are thicker in the lower portion of the dermis and become thinner as they approach the epidermis. Elastin differs from collagen not only structurally but also chemically. Desmosine is an amino acid unique to elastin. About 0.4% of the dry weight of the dermis is made up of fine branching fibers that, unlike collagen, stain black with silver stains and are known as reticulin. Their axial periodicity is identical to that of collagen. Reticulin fibers in the papillary dermis serve to anchor the basal lamina [17].

c. Ground Substance

The amorphous ground substance in which the fibers and cells lie contains acidic GAGs. In dermis the major forms are hyaluronic acid, chondroitin sulfate, and dermatan sulfate.

d. Nerves

The skin is supplied with both sensory and autonomic nerves. It is innervated with about one million afferent nerve fibers; most terminate in the face and extremities, and relatively few supply the back. The sensory nerves, unlike autonomic nerves, possess a myelin sheath up to their terminal ramifications.

The papillary dermis is heavily innervated with unmyelinated nerve fibers that transmit the sensations of temperature, pain, and pruritus. Three types of special nerve end organs also exist in the dermis. Vater-Pacini corpuscles are large end-organs that are located in the deeper portions of the dermis and subcutis and mediate a sense of pressure. They measure up to 1 mm in diameter and have their greatest concentration at the tips of the fingers and toes. A few are present in the nipple and anogenital regions. Meissner corpuscles are located in the dermal papillae and mediate the sense of touch. They occur only on the ventral aspects of the hands and feet and are most concentrated in the fingertips. The mucocutaneous end-organs are found in the papillary dermis of the modified hairless skin of the glans, the prepuce, the clitoris, the labia minora, the perianal region, and the vermilion border. The autonomic nervous system supplies fibers

to the arrector pili muscles, the blood vessels, and the eccrine and apocrine glands. The sebaceous glands are not innervated, and their functioning depends on endocrine stimuli. The autonomic nervous system controls vasoconstriction, contraction of the arrector pili muscles, and glandular secretion.

e. Vasculature

The dermal vasculature consists of intercommunicating plexuses. The subpapillary plexus lies within the papillary dermis and runs parallel to the epidermis to furnish a supply of capillaries, arterioles, and venules to the dermal papillae. The deeper plexuses are composed of larger vessels and surround hair follicles and eccrine glands. The dermal lymphatics are associated with the vascular plexuses.

f. Muscles

Smooth muscle occurs in the skin as the arrector pili muscles of the hair to pull the follicle upward with contraction. There are also smooth muscles fibers in the scrotum and the areolas. Striated muscle occurs in the skin within the neck as the platysmas and in the muscles of expression of the face. Special aggregates of smooth muscles are found between the arterioles and the venules in the skin. These serve to shunt blood from the arterial to the venous system directly and thus bypass the capillary system.

PART 3.1.7 APPENDAGEAL STRUCTURES

a. Eccrine Sweat Glands

Humans have several million eccrine sweat glands distributed over most skin sites, but they are more concentrated in the axilla, forehead, palms, and soles. In some areas they number as many as 600 glands per square cm. Eccrine sweat glands are the most numerous skin appendages and are responsible for the production of sweat. They have a cylindrical spiral duct lined with epidermal cells extending from their visible opening in the epidermis down into the deep dermis, where the duct becomes coiled and convoluted into a ball [18]. This secretory coil manufactures the odorless sweat, which rises up the duct to be released on the skin surface. It is thought that the duct of the gland has the ability to modify the sweat as it flows upward by removing salts or water.

The sweat glands control both body temperature and excretion, and they are

under the control of the cholinergic nervous system. The evaporation of sweat has a cooling effect. The glands respond to environmental temperature but also to other stimuli, such as UV light, emotional stress, and increases in body temperature. On the palms and soles, the secretion from the glands serves to increase surface friction.

Sweating appears to involve activation of myoepithelial cells, which line the ducts of the glands. Although sweating is considered to be a continuous process, it seems that sweat is ejected in small bursts, suggesting a peristaltic action by the ducts. The composition of eccrine sweat is similar to that of plasma, although more dilute, and was documented about 40 years ago. It includes, in decreasing relative concentration (mg %): Cl^- (320), Na^+ (200), lactic acid (35), K^+ (20), urea (15), ammonia (5), Ca^{++} (2), glucose (2), Mg^{++} (1), amino acid (1), and creatinine (0.3).

b. Apocrine Glands

The apocrine glands are tubular glands attached to the hair follicle and, like the sebaceous glands, develop in association with it [19]. Although rudiments are found covering the entire surface of the fetus, the glands become canalized and functional almost exclusively in selective areas including: the axillae, the anogenital regions, the areola, the external auditory canal, and the eyelids. In humans, apocrine gland secretions are milky and viscous but without odor. Odor production is related to bacterial action on apocrine secretions at the skin surface.

After puberty, apocrine gland secretion is in response to emotive stimuli. Adrenergic nerves control secretory activity, in contrast to the cholinergic control of eccrine function. The function of the glands in the human species has been much debated; studies have demonstrated that the apocrine skin glands of mammals produce various glycoconjugates and antimicrobial substances, which may serve as a nonspecific defense on the skin surface [20]. In other mammals the glands serve a sexual function.

c. Sebaceous Glands

Sebaceous glands [18] secrete sebum, which forms the majority of the lipid that covers the skin and hair. They are found in all areas of human skin except the palms, soles, and dorsum of the feet. Sebaceous glands are usually associated with hair follicles, except for those on the nipples, areola, and labia minora. The greatest concentrations (reportedly as high as 400–900/cm) are found on the

scalp, face, upper chest, and shoulders.

The glands are holocrine and thus form their secretion by decomposition of their cells. New cells are formed continually from the lining of the gland by cell division to replace those lost. No motor innervation has been demonstrated in humans. During the generation of sebum, cells at the periphery of the lobule undergo division. As the daughter cell moves toward the center of the lobule, it synthesizes lipids. As the sebum accumulates, the cell increases in volume as much as 150-fold. When synthesis is complete cell rupture occurs. This process from cell division to rupture requires approximately 14 days. The relatively long delay must be taken into consideration when designing drugs, cosmeceuticals, and therapies aimed at altering sebum.

Sebaceous gland activity is under hormonal control. It is stimulated by androgens of both gonadal and adrenal origin. In human males the glands are minute during the prepubertal period but undergo vast enlargement at puberty, when their output increases more than fivefold. Eunuchs secrete about half as much sebum as normal males but substantially more than boys; it seems that the secretion is dependent on adrenal androgens. Adult women secrete only a little less than men; their sebaceous activity appears to be maintained by androgens from the ovary and the adrenal cortex. Estrogens and anti-androgens, such as cyproterone acetate, inhibit sebaceous secretion in humans. On the other hand, relatively small doses of potent androgens can cause enlargement of the glands and an increase in sebum production.

Human sebum is composed of triglycerides (57.5%), wax esters (26.0%), squalene (12.0%), free fatty acids (10%), and, to a minor extent, cholesterol and cholesterol esters. Epidermally derived lipids differ in lacking wax esters and squalene and having much higher proportions of cholesterol esters and cholesterol. There are marked differences in sebum composition among species. The origins of sebaceous lipids and their composition are different from those of the epidermal lipids [21]. The purpose of sebum is not entirely understood, but sebum has been shown to have thermoregulatory functions, and plays a role in the regulation of immunological functions and inflammatory processes. In addition, sebum contains lipids with antimicrobial activity [22]. While excessive sebum production has been associated with the development of acne vulgaris, lack of sebum production in prepubertal children is not associated with any skin abnormalities.

PART 3.1.8 HAIR

The hair follicle is quite variable, depending on its location. In adults, deep terminal hairs are found on the scalp and male beard area. Hair on the extremities and trunk is located more superficially in the skin. Vellus hairs are present on the female face and on the nonbearded areas of the male face. Lanugo is soft fine hair that covers the fetus and is shed prior to birth.

In general, the cross-sectional shape of terminal Caucasian scalp hair is round and somewhat curly; African American scalp hair is oval, sometimes flattened, and usually kinky; hair in Asians is round in cross-section and straight. These relationships do not apply to pubic hair, beard hair, and eyelashes, which have similar features in all races and are typically oval.

Hair color is due to the distribution of melanosomes within the hair shaft produced by melanocytes in the hair bulb. These are transferred to cells of the hair matrix similar to the transfer from melanocytes to keratinocyte in the epidermis. Three types of melanosomes are present in hair. Eumelanins are seen in dark hair, and pheomelanins predominate in blond hair. The intensity of color is related to the number of fully melanized melanosomes produced. Gray hair and white hair are due to a decreased number of melanocytes that produce fewer melanosomes.

Despite the vast body of knowledge regarding the anatomy, biology, and function of hair, humans are still unable to induce hair regrowth in the many disorders that result in hair loss, or to induce permanent hair removal in states of excessive hair. The cost of hair care in terms of time and money spent is huge in many cultures, and the psychological impact of hair disorders should not be underestimated.

PART 3.1.9 NAILS

The nail plate is composed of keratinized cells that originate in the nail matrix. As discussed previously, there are no keratohyalin granules. The proximal nail fold forms the cuticle. The nailbed does not contribute to the development of the nail plate but serves as a base for the adherent keratinous nail plate.

PART 3.1.10 BARRIER FUNCTION AND PERMEABILITY

For the cosmetic industry, by and large, the skin has been synonymous with the epidermal permeability barrier, located in the *stratum corneum*. This is a

somewhat restricted view, but nevertheless remains in place due to the fact that skin moisturization—a function that is of prime interest to the industry—is dependent on a functional permeability barrier. As the saying goes, a good moisturizer is not necessarily a barrier product, but all barrier products are good moisturizers. The two-compartment, "brick and mortar" organization of the healthy *stratum corneum*, with its organized lipid membranes, do "lock in" moisture and prevent dry, chapped skin. However, the significance of other types of barriers in the skin, i.e., UV barrier, antioxidant, and antimicrobial defenses have all begun to be appreciated and emphasized, as evidenced by the proliferation of active ingredients targeted to them. This growing recognition, in concert with an improved understanding of the other areas of the skin, is critically important to novel thinking leading to new functional ingredients for this important cosmetic and personal care category.

a. The Barrier Property of Skin: A Historical Perspective

The barrier property of skin against influx and efflux of water was acknowledged as early as the 1800s, but the conclusive evidence was provided by the work of Irvin Blank and Scheuplein, who convincingly demonstrated its location in the *stratum corneum* (horny layer) [23]. The barrier properties are of interest to different scientific disciplines and industry; especially the pharmaceutical and personal care sectors that are interested in delivering drugs transdermally or active ingredients for topical delivery to improve the skin conditions (anti-aging, moisturizers, skin lighteners, etc.) respectively. For the dermatologists, inherited and acquired skin diseases such as various types of ichthyosis, atopic dermatitis, and psoriasis all have a compelling barrier dysfunction associated with it [24]. Extensive damage to the barrier, as in third-degree burns, can be lethal; attesting to the significance of a functional permeability barrier to prevent life-threatening dehydration of the body.

Details of barrier (and *stratum corneum*) formation, its structural complexity, and chemical characterization

Early investigators interpreted what appeared as a "basket weave" structure of the SC in routine histological studies as an indication that it is a passively occluding structure on the skin surface—a more or less uniform membrane functioning like "Saran wrap." Investigators who followed them have dispelled the notion of the SC as a "basket weave" structure passively occluding the surface. A battery of investigative techniques (electron microscopy, laser confocal microscopy, two-photon microscopy, as well as biochemical

characterization of lipids and proteins) have led to the understanding first of a "brick and mortar" organization of SC, and a later concept of the SC as being a composite material with several characteristics of a "smart" material [24]. In this latest model, the bulk of the SC is made up of corneocytes, which are the "bricks."

Before discussing the secretion of the lamellar lipids (pro-barrier lipids) and the further processing of the lipids in the SC extracellular domains (the "mortar"), a brief description of a multiplicity of the phenomena that occur in the SC is warranted.

These phenomena include: a description of the keratinocyte differentiation, synthesis of proteins (keratins, filaggrin, involucrin, loricrin, desmosomal components, enzymes involved in cornification) and lipids (which are packaged with lipid metabolizing enzymes and antimicrobial peptides within secretory organelles) in the form of lamellar bodies (Odland bodies, keratinosomes).

Keratinocytes (keratinizing epithelia) account for about 95% of the stratified epidermis (other cell types are melanocytes, Langerhans cells, Merkel cells), and based on its position within the strata as well as its progressive differentiation, is designated as belonging to several layers including: the basal layer (*stratum basale*), the spinous layer (*stratum spinosum*), the granular layer (*stratum granulosum*), and the cornified layer (*stratum corneum*). Epidermal stem cells that usually contribute to the maintenance of the interfollicular epidermis are located within the stratum basale. Their division (either symmetric or asymmetric) replenishes the keratinocyte population as cells from the basal layer move to the suprabasal layers and progressively undergo differentiation.

Stratum basale is made up of one layer of columnar basal cells attached to the basement membrane via hemidesmosomes. These cells display a high nucleo-cytoplasmic ratio, cell organelles like mitochondria and RER, as well as keratin filaments inserting into the hemidesmosomes. The cells also connect to the adjacent cells as well as those of the suprabasal cells via desmosomes. Biomarker proteins for the basal cells are keratins K14 and K5.

The *spinous* or prickly layer (*stratum spinosum*) above the *stratum basale* is named for its characteristic histological appearance due to the large numbers of desmosomes. In addition to the typical cell organelles, these cells often display a few lipid-enriched epidermal lamellar bodies (Odland bodies, keratinosomes, membrane coating granules). These will be described later in this section.

The biomarkers that distinguish this layer from the basal layer are keratins K1

and K10. *S.spinosum* also shows an increase in keratin filament content compared to *S.basale*. In the upper layers of *S.spinosum*, the cells begin to elongate and become slightly flattened. Above this layer is the *stratum granulosum*, a few layers of cells that are characterized by the presence of distinct, darkly staining (histological preparations) keratohyalin granules (KHK), composed of profilaggrin, loricrin, and a cystine-rich protein as well as keratins 1 and 10. The filaggrin subunits of profilaggrin play the role of matrix molecules to aggregate and align the keratin filaments.

In the upper granular layers of *stratum spinosum*, the keratin filaments are highly phosphorylated and have an extensive population of disulfide bonds compared to the cell layers below. As the cells of *stratum granulosum* stratify and differentiate, both the protein and lipid synthesis is ramped up, as evidenced from the boost in involucrin, KHKs, and LBs. In fact, the uppermost SG cells show an abundance of LBs (about 20% of the cell volume), which are apically polarized and poised to be secreted out. These details are not seen in histological preparations, but electron microscopy reveals both the internal structure of LBs, as well as tortuous and complex invaginations of the apical cell membrane at the *stratum granulosum–stratum corneum* interface. Secreted contents of LBs fill the interstices between the SG, and the overlying layer of *stratum corneum*, which still remain connected by means of desmosomes. The transition between the granular cell and the corneocyte presumably occurs within the span of a few hours, in response to several signals that involve but are not limited to an influx of calcium ions. The calcium signaling activates Ca++ dependant transglutaminase, which catalyzes the crosslinking of involucrin and loricrin. This process then forms a toughened “cornified envelope” immediately subjacent to the cell membrane. The phenomenon is also accompanied by dissolution of the nucleus, as well as cytosolic organelles, mediated by caspases, especially caspase 14. In fortuitous sections, electron microscopy captures the images of the “transitional cell,” while the images primarily display an abrupt transition between the nucleated SG and the non-nucleated, flattened, organelle-depleted and keratin-filled corneocytes (Figure 1).

Figure 1 (Conventional TEM shows terminal differentiation of nucleated keratinocytes to keratin filled, non-nucleated corneocytes)

Conventional electron microscopy has illustrated the nature of the SC organization (Reference Fig 1), which consists of the secretion of epidermal lamellar bodies (enriched in cholesterol, sphingolipids, fatty acids, and a battery of enzymes and antimicrobial peptides) at the *stratum granulosum–stratum corneum* interface. Hydrophilic tracers (such as colloidal lanthanum) injected subcutaneously have been used to visualize its efflux (and hence of water) through the epidermis. This efflux is blocked at the SG–SC interface where the LB contents occlude the extracellular space [25].

The lamellar bodies are organelles, ranging from 0.2 to 0.5 microns in diameter, which originate from the Golgi apparatus, and begin to appear from the *stratum spinosum* and increase in numbers towards the upper *stratum granulosum*. In the uppermost SG, they occupy nearly 20% of the cell volume, and are polarized towards the apical surface. A recent proteomic investigation [26] identified up to 985 different proteins within the LBs. Freeze fracture studies [27] as well as ruthenium tetroxide post-fixation techniques [28, 29] have unraveled the sequence of events that follow the secretion of epidermal lamellar bodies (Figure 2) (i.e., the fusion of disk-like contents of the LBs into multiple lamellae that occlude the intercellular spaces of the SC). Cytochemical localization, as well as experimental studies with various enzyme inhibitors, delineated the role of enzymes (lipases, phospholipase, sphingomyelinase, B glucocerebrosidase, cholesterol sulfatase) in conversion of these disks into compact lamellar structures that surround the corneocytes akin to the mortar in a brick (corneocytes) wall [4, 30-35]. Investigations on animal models with specific gene defects or knockouts further extended the knowledge on enzymes such as B glucocerebrosidase [36], stearoyl CoA desaturase (SCD) [37], and

Elov 14, which are involved in elongation of long-chain fatty acids crucial for ceramides [38, 39] as critical to barrier competency. In addition, proteolytic enzymes like kallikreins that lead to progressive dissolution of the corneodesmosomes for orderly desquamation of corneocytes [40, 41] and antimicrobial peptides such as beta defensins and cathelicidins [42] are co-localized to the lamellar bodies and within the extracellular matrix of SC, linking the formation of permeability barrier with an antimicrobial barrier [43] and innate immunity.

Figure 2 (Arrow indicates transformation of secreted LB contents to tight lamellae in upper SC)

The epidermal lamellar bodies initially considered to be discrete organelles (0.2 to 0.5 micrometers in diameter) were later found to form an interconnected network within the cells of the *stratum granulosum* [44], enabling a well-coordinated secretion in response to acute barrier disruption, as in tape stripping. Conventional TEM of a lamellar body in perfect cross-section shows the disc structures well, but not all LBs show such crisp morphology, a fact thought to reflect the plane of sectioning (oblique sections or grazing sections along the outer surface). LBs deficient in internal contents ("motheaten appearance") characterize a variety of skin dysfunctions [25], which correlate with permeability barrier defects and increased TEWL. Lamellar bodies are also crucial to the formation of "acid mantle" of the SC, which is of considerable interest to the cosmetic and personal care industry. These fascinating organelles consist of something resembling a cross between a lysosome and a secretory vesicle. They transport and secrete a diverse variety of molecules including: lipids, lipases, proteases, protease inhibitors, beta-glucocerebrosidase, antimicrobial peptides, etc.). An exhaustive proteomic and immunocytochemical analysis of lamellar-body enriched fractions and skin [26] identified about 985

proteins from the LB-enriched fraction: some secreted proteins, those with potential roles in desquamation, lysosomal proteins, related to transport and secretion of LBs, as well as proteins with putative roles in sorting of the LB cargo. It is possible that several subpopulations of LBs exist, and that the morphological diversity seen in electron micrographs may indeed reflect the pleomorphism of LBs, relating to either their contents or functional status. For example, hBD-2, which is virtually absent in normal skin keratinocytes, is induced when stimulated by cytokines or bacteria, and are localized to LB [45]. Most probably, some LBs synthesized in response to the bacterial challenge (LBS designed for microbial barrier?) must have a disproportionate content of the antimicrobial peptide (AMP), and it was speculated that pro-barrier lipids may not be the predominant components of this subpopulation [46]. They also may look different (deficient in lipids) or imperfect under the electron microscope. Could this be the basis of some of the abnormal, deficient LBs seen in various skin diseases such as psoriasis where keratinocytes show a high expression of AMPs? The study by Raymond *et al.* [26] showing 31 LB proteins corresponded to lysosomal components suggest that LBs are a new class of secretory lysosomes. Hence on a broad biological basis, they could be considered as “exolysosomes” involved in the matrix remodeling of the SC, or its exfoliation (the same way that lysosomes function in the molt of crustacean integument).

b. Stratum corneum

As the major barrier to flux of chemicals, water and other molecules into the skin, SC penetration pathways have attracted considerable attention. Since the SC is a two-compartment, composite system, three different routes of penetration have been proposed: transcellular, intercellular, and trans-appendageal (follicular) pathways (see for more details in the next section of this chapter). Much of the experimental results support the follicular and the intercellular pathway models. The intercellular pathway through the lipid domains is a tortuous path, and possibly both nonpolar and polar pathways are localized to this region. A true transcellular pathway (envisioned as a network of microor nano-channels) may only be opened up with the aid of microneedles or power-jet (gene gun) types of devices. The polar pathway may be located intercellularly and comprises aqueous regions surrounded by polar lipids, which create the walls of such microchannels as surmised by results of experiments designed to elucidate the contribution of extracellular lipids and intracellular

keratin to the structure of this pathway. This has been demonstrated by means of using baclofen, a model zwitterion, *in vitro* using human cadaver skin [47]. This contention is in conformity with the morphological characterization of a "pore pathway" through the mortar lipids, as proposed by Menon and Elias [48].

c. Other Barriers:

Other effective barriers in skin are antimicrobial barriers (AMP-mediated), immune barriers (innate and adaptive) mediated by Langerhans cells, oxidant barriers (keratinocyte and sebocyte derived antioxidants), and barrier to UV radiation (melanin-mediated). These diverse barriers are interdependent components of the skin barrier, as exemplified by facts that the permeability barrier recovery is faster/more efficient in darkly pigmented skin; the Langerhans cells are affected by a breach in the permeability barrier; and antimicrobial peptide synthesis is also up-regulated by challenges to permeability barrier.

As the tight junctions are also crucial for epidermal permeability barrier (the knockout models develop defective epidermal lipid synthesis and secretion), it is interesting to note that the Langerhans cells have been reported to extend their dendrites through the TJs, during the "search" mode when they scan the sub-SC domains for any sensitizers that have crossed the primary barrier. Such phenomena have only recently gained the attention of scientists and the appreciation of the cosmetic and personal care industry.

d. Penetration of Cosmetic Actives Through the Stratum Corneum

One of the most recurring debates in cosmetics has to do with the penetration of ingredients. How do manufacturers ensure optimal and targeted penetration of ingredients for efficacy at specific locations within the structure? What is the optimal penetration? How do water, lipophilic molecules, liposomes, or nanoparticles penetrate (if at all) through the *stratum corneum*, deep in the epidermis and below? From a scientific point of view, these questions are imperative towards the industry's goals of achieving improvements in compromised skin or anti-aging effects. We point out that the (global) regulatory definitions and distinctions drawn between "drugs" and "cosmetics" are carefully excluded in this scientific discussion and merely note that if one is to actually impact the multiplicity of biological phenomena occurring in the skin, then, inevitably, the schism between the legal definitions of "drug" and "cosmetic" must merge into a single "zone," and the difficulties in defining the

zone are indeed a challenge for all concerned.

In this section, we will take a somewhat different approach to exploring the question of penetration. We will focus on the *stratum corneum*, the outermost layer of human skin, which optimizes the delivery and efficacy of topical products in the skin. We will investigate now only how molecules are indeed able to penetrate this outermost layer, but also focus on the fact that even if they penetrate no deeper, they play an essential role in skin health and youthfulness.

As described above, the *stratum corneum* is the outermost layer of the skin. It consists of two distinct structural components: corneocytes and the intercellular lipid matrix. The corneocytes are differentiated keratinocytes (i.e., anucleated cells without intracellular organelles such as nuclei or mitochondria). They provide the structural support for the *stratum corneum* and act as a barrier against environmental aggression. Corneodesmosomes interconnect corneocytes as desmosomes interconnect keratinocytes in the epidermis. Essential corneodesmosomal proteins include desmocollin and desmoglein. The intercellular lipid matrix is located between corneocytes. The lipid species are composed of ceramides, fatty acids, cholesterol, and glucosylceramide derivatives. These lipids are synthesized by the keratinocytes in the upper layer of *stratum granulosum*. The covalent bonds between the ceramides of the intercellular lipid matrix and the structural proteins of corneocytes membrane create, through ester bonds, a dense and impermeable network [49].

Having identified what the *stratum corneum* is, let us now turn to the question at hand, namely: How do molecules of different sizes and forms, which have different physicochemical properties, penetrate into the *stratum corneum*?

Penetration

In general:

As discussed above, there are various ways for molecules (using passive diffusion) to penetrate the *stratum corneum*: intercellular, transcellular, intrafollicular, and polar. The intercellular pathway allows for a sinuous penetration of molecules between the corneocytes, through the intercellular lipids. The gaps between the intercellular lipids, which enable for penetration of molecules, measure 0.013 μm. This intercellular pathway is how most hydrophilic and lipophilic molecules penetrate through the *stratum corneum*.

The **transcellular pathway** involves corneodesmosomes creating bridges between cells and becoming sufficiently amphiphilic to enable transportation of molecules. The transcellular pathway is how amphiphilic molecules, as well as small other molecules, penetrate through the *stratum corneum*. These substances are able to integrate at the double layer of phospholipids constituting the cell membrane and can penetrate into the corneocytes. The speed of penetration by this pathway is very slow, but it is offset by the fact that the surface area is significant.

The **intrafollicular pathway** enables penetration through hair follicles (which account for 1 to 2% of the total skin surface). As the pilosebaceous follicles are located in deep invaginations of the epidermis, in the dermis, they lead molecules to the reticular dermis. Furthermore, hair follicles do not have a highly developed *stratum corneum*, which further facilitates penetration at this level. This intrafollicular pathway is how large molecules, which are typically highly insoluble, penetrate through the *stratum corneum*.

Finally, the **polar pathway** enables penetration of molecules through the polar pores. These pores are present between cells and are surrounded by polar lipids, which generate discontinuities in the organization of the lipids. This pathway is hydrophilic by nature. For example, sucrose penetrates into the epidermis this way.

Figure 1: Various pathways of penetration through the *stratum corneum*. There are various pathways for molecules to penetrate the *stratum corneum*: intercellular (penetration between the corneocytes through the intercellular lipids), transcellular (penetration through the corneocytes), intrafollicular (penetration through hair follicles), and polar (penetration through the polar pores).

Penetration of a substance through the skin depends on many parameters that can interact with each other. These parameters are biological factors such as skin condition and age, the site of application, and skin hydration. Physicochemical factors, in particular those related to the substances themselves, also play a role, for example the size of the molecules or their attraction with the surface of the skin. These different pathways are passive diffusions through the *stratum corneum*. Only small molecules (molecular weight below 500 Da) penetrate through the pathways. It should be noted that the vehicle that carries the active ingredient can facilitate the penetration through the *stratum corneum*.

Penetration of water into the *stratum corneum*

The *stratum corneum* is virtually impermeable except for a small quantity of water that is delivered to it by the epidermis. This transferrable water hydrates the SC's external layers, helps maintain its flexibility, and enables adequate enzymatic reactions and corneodesmolysis. The passage of water in the other direction, from the body through the skin into the outside environment, is called trans-epidermal water loss or TEWL. Transepidermal water loss is influenced by the concentration of water in the epidermis, by cellular integrity, by relative humidity, by diffusivity of water in the *stratum corneum*, and by the thickness of the *stratum corneum*.

The ability to maintain water in the skin depends on the arrangement of corneocytes, the composition and structure of intercellular lipids, and the

presence of naturally moisturizing factors. Naturally moisturizing factors are made of water-soluble compounds and absorb water from atmosphere; they are typically amino acids or other chemical substances that hold water and rehydrate the *stratum corneum*. Naturally moisturizing factors are formed during the epidermis differentiation and represent 10% of corneocyte mass.

Penetration of lipophilic molecules into the *stratum corneum*

Lipophilic molecules of low molecular mass enter the *stratum corneum* essentially by the intercellular pathway (a sinuous penetration between the corneocytes through the intercellular lipids). These intercellular spaces are composed of lipids providing the last step of epidermic differentiation (such as free or esterified sterols, free fatty acids, triglycerides, sphingolipides), arranged in oriented bilayers bounding hydrophilic and lipophilic areas. The higher the concentration gradient of cutaneous lipids in lipid bilayers, the lower the penetration speed of hydrophilic molecules will be. Hence, by increasing the fluidity of cutaneous lipids, penetration can be facilitated.

Penetration of liposomes into the *stratum corneum*

Liposomes are lipid vesicles that can be used as carriers for hydrophilic substances solubilized into aqueous domains, or lipophilic substances solubilized into lipidic membranes. These colloidal carriers are formed as concentric bi-molecular layers of phospholipids. The presence of cholesterol may improve the bilayer characteristics of liposomes by increasing the microviscosity/interfacial rheological behavior of the bilayer, thereby reducing the permeability of the membrane to water-soluble molecules, or stabilizing the membrane and increasing the rigidity of the vesicle.

Liposomes represent an alternative method to enhance the permeation of substances through the skin. There are five possible mechanisms for liposomes to penetrate into the *stratum corneum* [50]:

1. Liposomes release the active substances that then penetrate independently into the skin;
2. Liposomes are first absorbed and then fused with the skin's surface and constituents, then change the ultrastructure of the intercellular regions in the deeper layer of the *stratum corneum*. This decreases the impermeability of the *stratum corneum* and enhances the penetration of the encapsulated molecule [51];
3. Liposomes gravitate to the surface of the *stratum corneum*, resulting in a direct transfer of the molecule encapsulated from the liposome to the skin.

Vesicles could also fuse and mix with the lipids matrix of the *stratum corneum*, increasing the distribution of molecule into the skin [52];

4. Liposomes penetrate into the skin as an intact form. Although it is now generally accepted that conventional liposomes do not penetrate directly into the skin, this penetration mechanism has been described by Cevc *et al.* for deformable liposomes, also known as transfersomes [53].

In view of the presence of a surfactant in their bilayer, these vesicles exhibit viscoelastic properties that allow them to deform and pass between the cells of the *stratum corneum*, thus arriving intact into the epidermis. This mechanism is similar to the deformation of red blood cells as they change shape in order to pass through narrow blood vessels whose diameters are smaller than the undeformed blood cells. This penetration is made possible by the presence of a natural trans-epidermal water gradient, which is created by the hydrophilicity of phospholipids. Furthermore, these liposomes avoid dry environments and will follow the gradient of moisture, moving into the deeper layers and more hydrated skin.

5. Liposomes penetrate into the skin via cutaneous annexes such as sweat glands and hair follicles. An excellent review of these studies is provided in a review by Knorr et al [54].

The work with liposomes suggested that carrier/vesicle size may have an influence on skin penetration as well as deposition into hair follicles. The nanosizing approach has the potential to offer increased skin deposition of compounds and also the more efficient delivery of agents to hair follicles. Recent work by the group of Michniak-Kohn *et al.* suggests that some nanoparticulate carriers are able to deliver various lipophilic compounds to skin fairly efficiently while making sure that no compounds traverse the skin layers (no *trans*dermal penetration occurs). Additional benefits of these carriers included high solubilization (in one case 5000-fold) and improved stability of the encapsulated compounds. There are many other such examples in the literature, and nanosized particles have been used for a long time in sunscreen formulations and facial foundations.

Penetration of nanoparticles into the *stratum corneum*

The penetration of nanoparticles occurs through two possible pathways: intercellular and intrafollicular pathways. While the transfollicular pathway plays a central role in the study of the penetration of nanoparticles [55], it is not yet clear if nanoparticles penetrate into the hair follicles, or if they are stored in the outer layer of these hair follicles.

Intelligent Targeting Carriers

Intelligent Targeting Carriers have the ability to be recognized by fibroblasts, melanocytes, or adipocytes, thus delivering anti-aging, whitening, or slimming active ingredients, directly to the cells where they have to act.

Capsules are formed by a matrix of poly (lactic-co-glycolic acid) PLGA with an outer polyvinyl alcohol (PVA) shell with the addition of N-pantothenic-peptide [56]. A proper ligand is covalently bonded to the surface of the capsule. These ligands (mostly peptides) are recognized by receptors in the surface of the target cells. The cells are thus able to uptake the particle by endocytosis, while the particles are able to escape from the endosomal compartment, then degraded and therefore able to deliver the active to the cytoplasm.

Cruz *et al.* suggested that the PLGA capsules used as intelligent targeting devices increase the activity of the encapsulated active ingredients by concentrating them solely in the place where they can be biologically active. This is thus of interest to personal care products (anti-aging, whitening, tanning, slimming) [57].

Figure 2: Examples of penetration pathways by various molecules. The lipophilic molecules of low molecular mass penetrate through the *stratum corneum* by the intracellular pathway while the hydrophilic molecules prefer the polar pathway. The liposomes may penetrate via the transfollicular pathway and the transferosomes (i.e., deformable liposomes), pass between cells, and prioritize the intercellular pathway.

e. Penetration Versus Protection

It is not clear yet whether there truly is real *in vivo* penetration of the ingredients incorporated in cosmetic and personal care formulations. While many will propose that this means cosmetic formulations lack clear efficacy, we propose rather that the lack of penetration of a product's active ingredients need not be a

negative characteristic. Indeed, these ingredients still possess the ability to protect the *stratum corneum* against environmental stressors and damage. This concept is significant since the *stratum corneum* constitutes only 10% of the entire skin, yet it contributes to over 80% of the cutaneous barrier function. For example, the use of antioxidant molecules in cosmetic products can help the *stratum corneum* regenerate and protect itself and thus also regenerating and protecting the underlying epidermis and dermis from the harmful effects of UV and other environmental toxins.

In summary, while the individual penetration of water, lipophilic molecules, liposomes, and nanoparticles through the *stratum corneum* is becoming better understood when viewed through their intercellular, transcellular, intrafollicular, and polar pathways, the penetration mechanisms of cosmetic formulations remain poorly understood and are an area in need of further exploration.

In this review, we presented not only the known and various pathways of penetration through the *stratum corneum*, but also the fact that even if cosmetic formulations penetration is no deeper than the SC, their efficacy is demonstrable. Indeed, the *stratum corneum* represents the barrier function of skin, and thus needs to be protected from environmental toxins. By regenerating and protecting the *stratum corneum*, active cosmetic ingredients protect the epidermis and dermis.

PART 3.1.11 IMMUNOLOGICAL FUNCTION

The skin is the largest organ of the human body and possesses the unique function of protecting the body from allergens, chemicals, and microbial infection [58]. It is an immunoprotective organ that comprises of specialized cells called Langerhans cells in the epidermis. The dermal collagen network comprises of dendritic cells, T-cells and T-cell subtypes, B cells and mast cells. Langerhans cells are activated in response to allergen-mediated contact sensitization that elicits an immune response [59, 60]. Resident dermal dendritic cells in addition are induced in this phenomenon. As a result, the Langerhans cells migrate into the lymph nodes in response to chemokines such as CCL19. The migrated cells activate T-cells that undergo differentiation and proliferation, which results in the selective expansion of clonal populations of allergen-specific T-cells. The activation of Th1 and/or Th2 clonal T-cell populations ultimately results in allergen-specific sensitivity [61].

After first phase of infection with a pathogen, dendritic cells resident in the

dermis present antigens to naïve T-cells in the skin-draining lymph node, initiating an adaptive immune response that generates central memory T-cells and effector memory T-cells. At second round of infection, dendritic cells present antigen to central memory T-cells in skin-draining lymph nodes, giving rise to another population of effector memory T-cells that migrate into skin and attempt to destroy the infection.

There is a marked decrease in number of Langerhans cells with age. This affects the ability of TNF-alpha to induce Langerhans cell migration in response to an infection. There is an overall reduced cutaneous immune function with aging, thus rendering aged skin more prone to infections. There is a reduction in dendrite formation, reduction in Birbeck granules, and reduced antigen trapping capacity. Thus, skin immune function is associated with and decreases with aging.

UV radiation results in changes in the immune response. It suppresses the immune response and results in skin cancer development [62]. In harsh circumstances, it also destroys the Langerhans cells on skin.

Psoriasis is a common skin condition characterized by immune and genetic factors. The symptoms of the disease include skin lesions, dryness, redness, and irritation associated with inflammation. The process is an inflammatory skin disorder that results in dermal infiltration of T-cells, dendritic cells, macrophages, and neutrophils [63]. Anti-TNF alpha as well as anti-IL-12 and anti-IL-23 therapy and methods to exfoliate the skin lesions including reduction of inflammation are suggested interventions to treat psoriasis. A systems biology approach to characterize the transcriptome of the diseased state versus normal skin can be indicative of suggested therapeutic options to combat the disease.

PART 3.1.12 CYTOKINES

Cytokines are small proteins or glycoproteins produced by epidermal keratinocytes, Langerhans cells, monocytes/macrophages, fibroblasts, and lymphocytes in the skin. The cytokines bind to receptors on target cells and initiate an active immune response. The cytokines produced by keratinocytes have been most extensively studied. Keratinocytes produce interleukins (IL-1, IL-3, IL-6, IL-7, IL-9, IL-10), interferons (IFN-α, IFN-β), cytotoxins (TNF-α, TNF-β), colony-stimulating factors (G-CSF, MCSF, MG-CSF), and growth factors (bFGF, EGF, KGF, MGSA, NGF, TGF-α, TGF-β, PDGF) [64]. There is a relatively low basal level of cytokine production in normal healthy skin;

however, in the presence of a challenge (e.g., viral, bacterial, fungal), cytokine production increases. This is regulated by membrane proteins, known as toll-like receptors, that bind certain molecular components of pathogens [65]. Different toll-like receptors recognize different molecular components of the pathogen. The ligands include bacterial DNA, lipopolysaccharide, flagellin, β-glucan, *etc.* Cytokine production is altered in a variety of skin diseases.

PART 3.1.13 ENZYMES

Enzymes within the skin layers play an important role in maintaining the biochemistry of the skin, supporting the synthesis of its components and hence cell replication. This results in skin lipid production and the formation of the *stratum corneum* barrier properties that play such a crucial role in the penetration of cosmetic actives into the skin layers. In addition, the presence of enzymes influences how cosmetic actives and formulation excipients are metabolized. Also, enzymes function as skin protectors by scavenging free radicals and maintaining a pH gradient that influences the number and type of bacterial flora on the skin surface. They are one of the most essential components of the skin.

Enzymes in the dermis are responsible for continuous remodeling of the extracellular matrix [66]. In the basal layer of the epidermis, the metabolic activity of most cells is low. The exceptions are the few basal cells undergoing replication, where enzyme activity is high. As cells move up from the basal layer and enter into differentiation, there is a general increase in the enzymatic activities necessary to synthesize the components of desmosomes, keratohyalin granules, keratin proteins, and lipids [67]. In the spinous layer most energy is produced by mitochondrial activity, but as cells reach the upper granular layer, the mitochondria are degraded and energy production is dependent on anaerobic glycolysis with lactic acid as a by-product. Most of the protein synthesized during differentiation is keratin, which makes up the keratinocyte cytoskeleton [68]. Most of the lipid that accumulates with differentiation is packaged into lamellar granules [69, 70]. In the late stages of differentiation, the lamellar granules migrate to the apical end of the cell, and the bounding membrane of the lamellar granule fuses into the cell plasma membrane [71, 72]. The lipids and a battery of hydrolytic enzymes are extruded into the intercellular space. At about this time, some proteins from the keratohyalin granules are deposited on the inner surface of the plasma membrane [73]. A high-molecular-weight, histidine-rich and highly phosphorylated protein, profilaggrin, is dephosphorylated and

proteolytically clipped to small filaggrin units [74]. On passage into the *stratum corneum*, the filaggrin units induce aggregation of the keratin filaments into bundles of keratin that lie parallel to the plane of the skin. The filaggrin proteins are subsequently acted upon by proteases until they are degraded to their component amino acids [75]. This results in a very high osmotic strength in the corneocytes. At about the time of the transition from the granular layer to the *stratum corneum*, a calcium-dependant transglutaminase crosslinks the proteins on the inner surface of the plasma membrane through formation of isopeptide linkages [73]. There is further crosslinking of these proteins through the spontaneous formation of disulfide linkages. ω-Hydroxyceramides derived from the bounding membrane of the lamellar granules becomes ester-linked to the outer surface of this crosslinked protein layer [76]. Thus the original plasma membrane of the keratinocyte is replaced by a compound envelope consisting of a thick crosslinked band of protein with a covalently bound lipid layer on the outer surface.

The main source of carbon for epidermal lipid biosynthesis appears to be acetate from the circulation [77]. The rate-limiting enzyme for synthesis of fatty acids is acetyl-CoA carboxylase [78]. This is a biotin-dependent enzyme that converts acetyl-CoA to malonyl-CoA at the expense of one ATP. The fatty acids are incorporated into phosphoglycerides, sphingomyelin, and glucosylceramides in the viable portion of the epidermis. The rate-limiting enzyme in synthesis of sphingolipids is serine palmitoyl transferase [79], and the rate-limiting enzyme in cholesterol biosynthesis is β-hydroxymethylglutaryl-CoA reductase [80]. HMG-CoA reductase uses two molecules of NADPH to reduce HMG to mevalonate-CoA.

The lipids found in isolated lamellar granules include phosphoglycerides, sphingomyelin, glucosylceramides, and cholesterol [69]. One unusual glucosylceramide contains 30-through 34-carbon long ω-hydroxyacids amide-linked to a mixture of sphingosines and dihydrosphingosines with linoleate ester-linked to the ω-hydroxyl group and glucose β-glycosidically linked to the primary hydroxyl group of the base [81]. This unusual lipid is thought to be a major component of the bounding membrane of the lamellar granule, and is the precursor of the aforementioned covalently bound lipid of the envelope. Enzymes associated with the lamellar granules include ceramide glucosyl transferase indicating that lamellar granules arise from the Golgi apparatus, since this enzyme is considered a biochemical marker for the Golgi apparatus [82]. Hydrolytic enzymes associated with the lamellar granules include β-glucosidase,

acid phosphatase, amino-glycosidases, galactosidase, aryl sulfatase, phospholipase A, sphingomyelinase, and several proteases [69, 70, 83]. The combined action of some of these enzymes converts the cholesterol-phospholipid-glucosylceramide mixture extruded into the intercellular space into the cholesterol-ceramide-fatty acid mixture of the *stratum corneum*.

A minor lipid in the *stratum corneum* is cholesterol sulfate. This lipid has been shown to be a serine protease inhibitor [84]. It is thought that this protease inhibitor protects the corneodesmosomes, until in the outer layers of the *stratum corneum*, sterol sulfatase degrades the cholesterol sulfate, and this permits the serine proteases to break down the corneodesmosomes leading to desquamation.

3.1.14 ULTRAVIOLET RADIATION-INDUCED PHOTODAMAGE AND SKIN CANCER

Photocarcinogenesis is a cosmetic concern because the UV light-absorbing agents used in cosmetic (over-the-counter) sunscreens help to lower the incidence of skin cancer.

Exposure to UV radiation causes not only photodamage with the appearance of premature aging, but also precancers and cancers of the skin. Actinic keratoses are premalignant lesions in which the epidermis proliferates, producing hyperkeratotic lesions characteristic of photodamaged skin, especially in individuals with skin types I, II, and III. These lesions have a high percentage of DNA mutations, particularly at sites p53 and p16 which are characteristic of nonmelanoma skin cancers (NMSC). Although actinic keratoses occasionally spontaneously disappear, they should be medically treated to prevent their becoming squameous cell carcinomas.

Skin cancer has been classified as nonmelanoma skin cancer, and as cutaneous malignant melanoma. NMSC has the highest incidence of any cancer, approximately one million new cases each year in the United States. One in five Americans will get a skin cancer in the course of a lifetime. Mortality from NMSC is low, but morbidity can be considerable with possible disfigurement, especially on the face and neck.

Basal cell carcinoma (BCC) is the most common NMSC (equal to about 75% of the incidence of all skin cancers). Although BCCs do not metastasize, they are locally invasive and disfiguring if not treated early. Squameous cell carcinomas (SCC) account for about 20% of all skin cancers; approximately 2% of SCCs (particularly those originating on the head and neck) metastasize with possible

mortality. Melanomas make up about 5% of all skin cancers. If excised before they become invasive, melanomas can be definitively treated; however, if allowed to invade the dermis, melanomas metastasize with high mortality.

Sun exposure (and the use of tanning beds) is linked to the skin cancer epidemic as the incidence of NMSC increases in proportion to the cumulative sunlight exposure and is highest in people with skin types I and II. In the case of melanoma, the effects of UV are not clear except in lentigo maligna melanoma (a subclass of cutaneous melanoma), for which sun exposure has been shown to increase the incidence.

UV radiation causes skin cancer by inducing mutations in DNA which lead to damaging the ability of the skin cells to control proliferation. UVB harms mainly the epidermis and UVA, the dermis. The primary damage by UVB is *via* direct absorption by DNA to generate mutations through the formation of dimers between adjacent pyrimidine residues, leading to specific UVB "signature" mutations that can accumulate over time. UVB can also indirectly induce oxidative damage by the formation of reactive oxygen species (ROS) that indirectly damage DNA. If not repaired, both the direct and indirect DNA mutations persist through subsequent subdivisions causing precancers (actinic keratoses) and skin cancers. Reactive protective mechanisms by the epidermis cause thickening of the outer layers of the skin to create a UV-protective "outer shell" that gives an unattractive leathery texture and increased pigmentation that results in mottled discoloration, both of which are characteristic of the appearance of photoaging. UVA penetrates deeper to harm the dermis. UVA damages DNA indirectly through absorption by chromophones that generate ROS which mutate DNA *via* mutagenic oxidative intermediates. UVA also activates metaloproteinases which directly break down collagen and elastic tissue and act on other transcription factors to inhibit repair, thereby causing the sagging and wrinkles of photoaged skin.

Furthermore, recent research shows that UVA in combination with common environmental pollutants is synergistic in generating oxidative damage, thereby significantly increasing visible photodamage and the risk of skin cancer [84.5]. Polycyclic aromatic hydrocarbons (PAHs) such as benzo[a]pyrene (BaP) are ubiquitous in the air, food, and water as a result of incomplete combustion of fossil fuels (from power plants, car exhaust, heaters) and from cigarette smoke (the most prevalent indoor pollutant). These chemical pollutants exist at levels below damaging or tumorigenic levels. However, when combined with UVA exposure, there is a synergistic increase in oxidative damage with the

consequence of even more severe photoaging and increased incidence of skin cancer.

Thus UV radiation is a complete carcinogen; it can act alone as an initiator and a promoter in formation of cancer. UV can also act as a promoter with initiating events inside the cell, such as DNA mutations arising from DNA polymerase incorporation errors, depurination, deamination of 5-methylcytosine, or oxidative damage from free radicals. The cell can respond to the damage by repairing the DNA to avoid the effects of the mutations or, if the damage is too great, by inducing cell death through apoptosis to remove potential cancer cells from the population. Immunosurveillance aids recognition of potentially damaging mutated cells so that apoptotic mechanisms can be initiated. UVA decreases this cellular immune recognition and response.

PART 3.1.15 GENE EXPRESSION IN SKIN CARE

The Human Genome Project (HGP) was a 13-year effort that was coordinated by the U.S. Department of Energy and the National Institutes of Health. The project, which was completed in 2003, produced sequence information for the entire 3 billion base pairs in the human genome. The work cost more than one U.S. dollar per base pair, but generated over 265 times that in economic impact and job creation [85]. More importantly, the HGP gave rise to new, high-throughput technologies used to analyze genes and ultimately, a new field of science—*genomics*. From genomics, other high-throughput technologies were developed, giving rise to a suite of "omics" disciplines (e.g., proteomics and metabolomics). In combination, "omics" data provide a comprehensive view of how cells and biological systems work together in health and in disease. This information has enabled advances in dermatology and in the cosmetic and personal care industry [86]. In this section, the application of genomics-based methods to cosmetics and personal care is reviewed.

a. Genomics Technologies

Researchers have been studying the function of genes and proteins in the skin for decades using technologies such as Northern and Western blotting, and traditional polymerase chain reaction (PCR). These methods are labor intensive and only allow for analysis of a few genes or proteins at a time [87-92].

More recent technologies, including microarrays and quantitative real time PCR (qPCR), have enabled simultaneous analysis of thousands of genes and

more accurate quantification. Microarrays are now the "go-to" method for screening cells and tissues to identify novel biomarkers and understanding mechanisms of action. Both microarrays and qPCR technologies are used to detect changes in the sequence of DNA (i.e., mutations), as well as gene expression (an indicator of which genes are "turned on or off") in a given cell type. When a gene is "turned on," or activated, it is transcribed from DNA into a complementary strand of RNA (ribonucleic acid)—the RNA strand serves as a template for protein synthesis, directing the ribosome as to which amino acids to put together to form specific proteins. On the other hand, when a gene is "turned off," the cell stops transcribing the DNA strand and protein synthesis is terminated. Gene expression analysis is used to determine how cells and tissues are affected by specific conditions. The methods provide information at the molecular level as to how specific cellular functions are altered from normal homeostasis. Gene expression profiles can be used as a guide for creating products or targeted treatments that will convert an aberrant profile back to homeostasis.

b. Genomics and the Skin

To date, thousands of peer-reviewed research studies have been published using high-throughput genomics methods to elucidate molecular mechanisms associated with skin biology [93, 94]. Studies have been conducted across multiple disciplines, from embryonic development to aging, as well as all areas of skin ailments [95-97]. Many studies have identified unique gene expression profiles in skin disorders such as atopic dermatitis, acne, rosacea, and psoriasis [98-102]. A large number of whole-genome sequencing studies have been conducted to elucidate genetic mutations and predisposition related to rare skin conditions [103, 104].

Molecular studies of the epidermal skin barrier provide a good example of how genomics has improved our understanding of skin biology [105, 106]. The skin barrier is our body's first line of defense against environmental insults such as chemicals, radiation, pathogens, and other stimuli. The formation and maintenance of a functionally intact epidermal barrier involves the coordination of complex regulatory networks that involve the expression and interaction of hundreds of molecules. Some of these major processes include keratinocyte differentiation, apoptosis and maturation into corneocytes, cell migration and desquamation [107]. Gene expression studies have been used to identify the expression of key molecules involved in each one of these processes [108, 109].

In other studies, microarrays have been used to identify large sets of genes [110]. For example, Taylor *et al.* [111] used microarrays to identify genes expressed by differentiating keratinocytes at different time intervals. The study identified 1282 genes differentially expressed; specific genes include those that code for structural molecules and innate immune molecules. Other studies have identified microRNAs that regulate genes, such as p63, in proliferating and differentiating keratinocytes [112, 113]. Again, a better understanding of how specific molecules and pathways interact will facilitate the development of high-performing topical products for cosmetics and for treating specific skin conditions.

Additional studies have identified genetic mutations associated with compromised barrier function [114, 115]. Identifying mutations in genes, such as filaggrin, may aid in creating future diagnostic tools and advanced therapies. Filaggrin is a filament-associated protein that binds keratin fibers in skin epithelial cells. In the *stratum corneum*, filaggrin monomers are incorporated into the lipid envelope that forms the skin barrier. Filaggrin undergoes further processing in the upper *stratum corneum* to release free amino acids that assist in barrier formation and water retention. These proteins can also interact with keratin intermediate filaments. Other research has shown that CYP26b1 is expressed in keratinocytes in the epidermis. CYP26b1 is a member of the cytochrome enzyme superfamily, a group of enzymes that are essential for performing metabolic functions in the cell. CYP26b1 is essential for metabolism of retinoic acid [116]. Okana *et al.* [115] has recently demonstrated that genetic ablation of CYP26b1 disrupts epidermal barrier formation by inhibiting retinoic acid metabolism.

c. Gene Expression Analysis: A Breakthrough for Cosmetic Science

Gene expression technologies in cosmetics and personal care are now routinely used in product development pipelines. Drawing on information produced in basic research studies that identify molecular biomarkers associated with phenotypic endpoints, cosmetics and personal care companies are performing studies to define the skin's response to topical materials and formulations [117-120]. Skin care scientists are currently utilizing gene expression methods to screen raw materials for biological effects, identify dose-response relationships, and understand how combinations of ingredients may work together—this may be additive, synergistic, or hormetic.

To date, gene expression studies have been used to:

- Demonstrate efficacy and understand mechanisms of action
- Streamline product formulations during development
- Create performance products that ultimately improve marketability, consumer confidence and brand loyalty

While most work has been conducted to improve product formulations and validate efficacy, genomics-based screening methods may also provide new and improved tools for assessing safety and toxicity [121]. This will require carefully planned studies to develop and validate improved tissue models that contain immune cells as well as sophisticated informatics and algorithms to easily analyze and interpret the datasets.

d. Challenges

Understanding how specific patterns of gene expression translate into a biological response is one of the greatest challenges in interpreting high throughput genomics data. For now, genomics data are best used as a roadmap to generate hypotheses and guide follow-on studies that utilize additional cell biology methods better suited for interrogating functional relationships.

Another challenge in conducting genomics-based studies for cosmetic science is the lack of fully representative experimental tissue models. Studies conducted for the cosmetics industry are typically carried out using *in vitro* cell cultures or artificial skin. While these models provide useful information regarding the keratinocyte and fibroblast response, they lack melanocytes, Langerhans cells, and an epidermal barrier consistent with *in vivo* human skin. *In vitro* models are an ideal tool for conducting early screening studies that should be followed up with *in vivo* clinical work.

e. Looking Ahead

Since the inception of genomics, newer, state-of-the-art technologies such as NextGen sequencing have been developed. These methods can rapidly sequence the entire genome in several days, perform RNA sequencing, and analyze epigenetic mechanisms (i.e., DNA methylation). While epigenetics is now a popular buzzword in cosmetic science, a greater understanding of these mechanisms in skin biology will help elucidate phenomena such as aging, photoaging, and skin disease. Groundbreaking epigenetic research in skin biology is beginning to emerge and will soon be translated into product development.

Another emerging concept is the promise of “personalized skin care” [122].

This approach uses an individual's genetic footprint to develop skin care products to address the specific needs of an individual. Companies are beginning to explore this opportunity, and there will most likely be an increased amount of data and ultimately, product development using the "personalized medicine" approach in the next few years.

GLOSSARY

1. Epidermis - composed of the outermost layers of cells in the skin—"epi" in

Greek meaning “over” or “upon,” which together with the dermis forms the entire skin layer termed the cutis.

2. Dermis - a layer of skin between the epidermis and subcutaneous tissues that consists of connective tissue and cushions the body from mechanical stresses. It is divided into two layers, the area adjacent to the epidermis called the papillary region and a deeper and thicker area known as the reticular dermis.
3. *Stratum corneum* (Latin for “horned” or “horny” layer) - the outermost layer of the skin, consisting of dead cells (corneocytes) that lack nuclei and organelles. This layer is responsible for the barrier function of skin.
4. Glycoaminoglycan - any of a group of high-molecular-weight linear polysaccharides with various disaccharide repeating units and usually occurring in proteoglycans, including the chondroitin sulfates, dermatan sulfates, and hyaluronic acid. Abbreviated as GAG.
5. Collagen - protein made up of amino acids, which are in turn built of carbon, oxygen, and hydrogen. Collagen contains specific amino acids—glycine, proline, hydroxyproline, and arginine. There are many types of collagen that have been identified. Collagen is synthesized most commonly by fibroblasts.
6. Keratin - a family of fibrous structural proteins. Keratin is the key structural material making up the outer layer of human skin. It is also the key structural component of hair and nails.
7. Keratinocyte - the main cell type in the epidermis, the outermost layer of the skin. Those keratinocytes found in the basal layer (*stratum germinativum*) of the skin are sometimes referred to as “basal cells” or “basal keratinocytes.”
8. Corneocyte - a terminally differentiated keratinocyte that forms part of the stratum corneum, the outermost part of the skin. The cell is regularly replaced through desquamation and renewal from the lower epidermal layers, making it an essential part of the barrier property of the skin.
9. Fibroblast - a type of cell that synthesizes extracellular matrix and collagen, the structural framework for the skin, and plays a critical role in wound healing. Fibroblasts are the most common cells of connective tissue and in particular the dermal layer of the skin.
10. Cytokine - (Greek “cyto,” cell; and “kinos,” movement) are any of a variety of compounds secreted by specific cells of the immune system. They carry signals locally between cells and thus have an effect on other cells. They are a category of signaling molecules that are used extensively in cellular communication. They can be proteins, peptides, or glycoproteins.

11. Merkel cells - clear cells found in the *stratum basale* (at the bottom of sweat duct ridges) of the epidermis, approximately 10 µm in diameter. They also occur in epidermal invaginations of the plantar foot surface called rete ridges. Most often they are associated with sensory nerve endings, when they are known as Merkel nerve endings.
12. Langerhans cells - dendritic cells (antigen-presenting immune cells) of the skin, containing large granules called Birbeck granules. They are present in all layers of the epidermis, but are most prominent in the *stratum spinosum*. They also occur in the papillary dermis, particularly around blood vessels.
13. Dendritic cell - immune cell forming part of the immune system. Main function is to process antigen material and present it on the surface to other cells of the immune system. Dendritic cells are present in tissues in contact with the external environment, such as the skin (where there is a specialized dendritic cell type called Langerhans cells).
14. Birbeck granule (also known as Birbeck bodies) - rod-shaped cytoplasmic organelles with a central linear density and a striated appearance.
15. Fillagrin - a filament-associated protein that binds to keratin fibers in epithelial cells.
16. Involucrin - a protein component of human skin. In humans it is encoded by the *IVL* gene. In binding the protein termed loricrin, involucrin is involved in the formation of the cell envelope that protects corneocytes in the skin.
17. Melanin (from the Greek “melas” meaning “black”) - a natural pigment in skin derived from the amino acid tyrosine.
18. Melanosome - an organelle containing melanin, the most common light-absorbing pigment found in the mammalian kingdom.
19. Pheomelanin - yellow to red-brown pigment produced by melanocytes.
20. Eumelanin - black to brown pigment produced by melanin.
21. Golgi apparatus (also known as the Golgi complex, Golgi body, or simply the Golgi) - an organelle found in most eukaryotic cells. Part of the cellular endomembrane system, the Golgi apparatus packages proteins inside the cell before they are sent to their destination; it is particularly important in the processing of proteins for secretion.
22. Macrophage - any of the large, mononuclear, highly phagocytic cells derived from monocytes that occur in the walls of blood vessels and in loose connective tissue. Macrophages are usually immobile but become actively mobile when stimulated by inflammation; they also interact with lymphocytes

to facilitate antibody production.

23. Elastin - a key extracellular matrix protein that is critical to the elasticity and resilience of many tissues including skin.
24. Reticulin - name given to the chemical substance of reticular fibers, which were formerly thought to be distinct from collagen by reason of their distinctive structure and staining properties but are now regarded as type III collagen.
25. Apocrine gland - a sweat gland composed of a coiled secretory portion located at the junction of the dermis and subcutaneous fat, from which a portion inserts and secretes into the infundibular portion of the hair follicle.
26. Eccrine gland - a sweat gland that is not connected to hair follicles. It functions by responding to elevated body temperature due to heat or physical exercise.
27. Sebaceous gland - small oil-producing gland usually attached to hair follicles and releasing a fatty substance, sebum, into the follicular duct and thence to the surface of the skin.
28. Sebum - consists of a mixture of fats (triglycerides, wax esters, squalene, and cholesterol) and cellular debris, which is discharged through the sebaceous duct.
29. Kallikreins - these belong to a class of serine proteases with a high degree of substrate specificity. The enzymes are structurally related to trypsin. Kallikrein (kininogen, kininogenase = EC3.4.21.8) cleaves proteins between arginine and lysine residues.
30. Keratinosomes (otherwise known as membrane-coating granules [MCGs], lamellar bodies, lamellar granules or Odland bodies) - secretory organelles found in keratinocytes. Keratinosomes fuse with the cell membrane and release their contents into the extracellular space.
31. Androgen - a male sex hormone such as testosterone.
32. Ichthyosis - a family of genetic skin disorders characterized by dry, scaling skin that may be thickened or very thin.
33. Atopic dermatitis (eczema) - an itchy inflammation of the skin. It is usually a chronic condition that may be accompanied by other conditions such as asthma.
34. Psoriasis - a chronic skin disease that affects the life cycle of skin cells. It causes cells to build up rapidly on the surface of the skin, forming thick silvery scales and itchy, dry, red patches that are sometimes painful.

35. Transepidermal Water Loss = TEWL - This is defined as a measurement of the water amount that diffuses or evaporates from inside the body through the epidermis to the surrounding atmosphere. TEWL can increase due to disruption of the skin barrier through wounds, scratches, burns, exposure to solvents or surfactants, extreme dryness) and is affected by humidity, temperature, season, and moisture content of the skin.
36. Liposomes - nano/micro-size spherical drug carriers that can be produced from natural or synthetic phospholipids and cholesterol. They form spontaneously when phospholipids are combined with water and bilayered spheres form, since the phospholipid molecules orient themselves according to their polarity (one end of each molecule is water soluble, while the opposite end is water insoluble).
37. Rheology - a science dealing with the deformation and flow of matter and including the measurement of viscosity.
38. Colloids - a solution that has particles ranging between 1 and 1000 nanometers in diameter and evenly distributed throughout the solution.

ABSTRACT

Cosmetologists and aestheticians are daily faced with a wide variety of clients. In order to provide their skin with optimal health and beauty services these practitioners must accurately look at skin of different races and determine appropriate treatment protocols. Early projections of the changing global skin color landscape have now been proven to be accurate, and the main categories of skin color are no longer just Caucasian-white, but have evolved towards a dramatic escalation of brown, black, yellow, and the many shades in between.

The current scale available to the industry is the Fitzpatrick scale (Figure 4), which was developed in 1975 by Harvard dermatologist Dr. Thomas B. Fitzpatrick. The Fitzpatrick scale is described in this chapter as a custom and practice foundation for current practitioners. It is simple and easy to use; however, the method leaves a gap in the ability to classify skin in light of the evolving epidemiological landscape, and the system fails to accurately predict skin type and precautions for race, complexions, and skin characteristics.

Extensive research over the last decade reveals that beyond color alone, other key factors such as race, country of origin, and ethnicity play an important role in how the skin will respond to cosmetic and personal care products and procedures. Further, when the world is viewed as a whole, and countries are thoughtfully divided into sections, there appears to be an order that helps define how skin from similar regions acts in similar ways. This observation provides the basis for a new, more detailed skin classification scale. A proposal for this

new scale is at the heart of the current chapter. The scale has been called the EP Global Skin Classification Scale (Figure 1) and is focused on an all-encompassing global approach that is comprehensive and easy to use for the skin care professional. (Figures 2 & 3 show additions to EP Global Skin Classification Scale.) **TABLE OF CONTENTS**

3.2.1 Why we need an updated Skin Classification Scale

3.2.2 The methodology in which the study was conducted:

3.2.3 Summary, Analysis

3.2.4 Where Methodology Meets Results

3.2.1 WHY WE NEED AN UPDATED SKIN CLASSIFICATION SCALE

The changing of global skin color landscape is now a reality; the majority is no longer just Caucasian but Asian, with the many shades of yellow undertones and shades ranging from light to dark olive complexions. The common skin conditions among the different races also differ; therefore skin has to be diagnosed and treated according to color and race and a one-size-fits-all method of the past no longer works.

The world is divided geographically into continents:

- Asia is the most populous continent, with its 4.2 billion inhabitants accounting for over 60% of the world population. (The world's two most-populated countries alone, China and India, together constitute about 37% of the world's population).
- Africa is the second-most-populated continent, with around 1 billion people, or 15% of the world's population.
- Europe's 733 million people make up 11% of the world's population.
- Latin American and Caribbean regions are around 600 million (9%).
- Northern America, primarily consisting of the United States, and Canada, has a population of around 352 million (5%).
- Oceania, the least-populated region, has about 35 million inhabitants (0.5%).

Worlds Population by Race

East Asian 24% (Korea, Mongolia, China, Japan)
South Asian 21% (India, Sri Lanka, Pakistan, Bangladesh, Nepal)
Southeast Asian 9% (Cambodia, Burma, Philippines, Malaysia)
Black 15%
White 15%
Hispanic 8%
Middle Eastern 8%

USA

The USA is a diverse country of many races; the chart below shows the growth and census population over the past decade.

Race	**Census 2010, population**	**Percent of population**	**Census 2000, population**	**Percent of population**
Total Population	**308,745,538**	**100.0%**	**281,421,906**	**100.0%**
Single race				
White	196,817,552	**63.7**	211,460,626	**75.1**
Black or African American	37,685,848	**12.2**	34,658,190	**12.3**
American Indian and Alaska Native	2,247,098	.7	2,475,956	**0.9**
Asian	14,465,124	**4.7**	10,242,998	**3.6**
Native Hawaiian and other Pacific Islander	481,576	**0.15**	398,835	**0.1**
Two or more races	5,966,481	**1.9**	6,826,228	**2.4**
Some other race	604,265	.2	15,359,073	**5.5**
Hispanic or Latino	50,477,594	**16.3**	35,305,818	**12.5**

NOTE: Percentages do not add up to 100% due to rounding and because Hispanics may be of any race and are therefore counted under more than one category.

Source: U.S. Census Bureau: National Population Estimates; Decennial Census.

The current scale that has been industry standard for the past 38 years is the Fitzpatrick scale.

The Fitzpatrick Classification Scale was developed in 1975 by Harvard Medical School dermatologist Thomas Fitzpatrick, MD, PhD. This scale classifies a person’s complexion and their tolerance of sunlight. It is used by many practitioners to determine how someone will respond or react to facial treatments, and how likely they are to get skin cancer.

Skin Type	Skin Color	Characteristics
I	White; very fair; red or blond hair; blue eyes; freckles	Always burns, never tans
II	White; fair; red or blond hair; blue, hazel, or green eyes	Usually burns, tans with difficulty
III	Cream white; fair with any eye or hair color; very common	Sometimes mild burn, gradually tans
IV	Brown; typical Mediterranean caucasian skin	Rarely burns, tans with ease
V	Dark Brown; mid-eastern skin types	very rarely burns, tans very easily
VI	Black	Never burns, tans very easily

Fitzpatrick Classification Scale (Table 1)

The method leaves a gap in the ability to classify skin in light of the evolving epidemiological landscape, and the system fails to accurately predict skin type and precautions for race, complexions, and skin characteristics.

The EP Global Skin Classification tool was designed to fill the gaps by expanding the categories and taking into consideration global skin. The following categories were implemented:

- Race
- Country of Origin
- Complexion
- Skin Characteristics
- Skin Type
- Precautions

(See Figures 1-3)

EP Global Skin Classification Scale

EP #	Race	Country of Origin	Complexion	Skin Characteristics	Skin Type
I	Caucasian I	Belgium, Denmark, Estonia, Finland, Germany, Iceland, Ireland, Latvia, Liechtenstein,	Pale, Very Fair. Ruddy	Sensitive, thin fragile skin. Burns easily in sun, never tans, Age's rapidly. Fine wrinkling occurs early.	Hyper-Sensitiv Environmental Damage. Acne

		Lithuania, The Netherlands, Norway, Sweden, Switzerland, United Kingdom, Canada,Greenland	Freckled complexion.	Orange peel skin as they age. Scars usually thin. Skin tends to be dry.	Prone. Skin Ca most common this type.
II	Caucasian II	Andorra, Austria, Belarus, Bosnia & Herzegovina, Croatia, Czech Rep. France, Greece, Hungary, Italy, Kosovo, Luxembourg, Moldova, Monaco, Montenegro, Poland, Portugal, Romania, Russia, San Marino, Serbia, Slovakia, Slovenia, Spain, Ukraine, Vatican City, USA.	Fair. Light Olive undertones.	Sensitive, fairly thin skin. When exposed to sun will first burn then tan. Signs of aging appear early. Nominal Scarring. Dry to normal skin.	Sensitive Phot Damage Prema Aging Acne Pr Greater chance skin cancer.
III	Caucasian III	Australia, Bulgaria, Cyprus, Georgia, Greece, Macedonia, Malta, New Zealand, Turkey, South Africa, Zimbabwe	Fair Medium Olive undertones.	Seldom burns when exposed to sun, will tan, excessive exposure to sun will cause the skin to look leathery. Signs of aging appear later. Fine wrinkling less common. Scarring maybe thicker and darker. Normal to oily skin.	Environmental Damage Exces Photo damage Prone Skin Ca common
		Argentina, Belize,			

IV	Hispanic/Latino	Bolivia, Brazil, Chile, Colombia, Costa Rica, Ecuador, El Salvador, Falkland Islands (Malvinas), French Guiana, Guatemala, Guyana, Honduras, Mexico, Nicaragua, Paraguay, Panama, Peru, Suriname, Uruguay, Venezuela.	Olive undertones. Medium to Dark Olive; wide range of Olive tones.	Depending on skin tone will rarely burn; will always tan, aging process is moderate. Darker, thicker scarring. Normal to oily skin.	Photo Damage Environmental Damage Hyperpigment Acne Prone Sk Cancer less common
V	Mediterranean/Asian I	Afghanistan, Albania, Algeria, Armenia, Azerbaijan, Bahrain, Iraq, Iran, Israel, Jordon, Kazakhstan, Kuwait, Kyrgyzstan, Lebanon, Oman, Palestine, Qatar, Saudi Arabia, Syria, Tajikistan, Turkmenistan, UAE, Uzbekistan, Yemen	Medium-Dark Olive undertones	Seldom burns, will tan. Aging process is moderate. More advanced if over exposed to sun. Wrinkles appear later in more localized areas. Darker, thicker scarring. Normal to oily skin.	Photo Damage Environmental Damage Hyperpigment Melasma Acne Prone Post Inflammatory Hyperpigment (PIH) Skin Ca rare
VI	Asian II	Brunei Darussalam, Cambodia, China, Hong Kong, Indonesia, Japan, Korea, Laos, Macao, Malaysia,	Medium – Dark Yellow-	Seldom burns, tans about average. Ages well, signs of aging appear late. Prone to	Hyperpigment Melasma Acne Prone Post Inflammatory

		Mongolia, Philippines, Singapore, Taiwan, Thailand, Timor Leste, Vietnam.	Olive undertones.	Pigmentation changes. Scarring can be thicker and darker. Normal to oily skin	Hyperpigment (PIH) Skin Ca very rare
VII	Asian III	Bangladesh, Bhutan, India, Maldives, Myanmar (Ex-Burma), Nepal, Pakistan, Sri-Lanka, Tibet.	Light to dark Olive tones. Yellow undertones	Rarely burns, always tans. Pigmentation changes may occur with over exposure to sun. Ages well, signs of aging appear late. Fine wrinkles do not occur. Darker thicker scars more common	Hyperpigment Melasma Activ Acne/ Acne Pr Post Inflamma Hyperpigment (PIH) Skin Ca very rare.
VIII	Native Hawaiian and other Pacific Islanders	Fiji, French Polynesia, Guam, Kiribati, Marshall Islands, Micronesia, New Caledonia, New Zealand, Papua New Guinea, Samoa, Solomon Islands, Tonga, Vanuatu.	Medium-dark Olive tones.	Seldom burns, tans well, thicker skin allows better sun tolerance. Ages moderately. Thicker and darker scars. Thick Oily skin.	Photo Damage Environmental Damage Hyperpigment Acne Prone Sk Cancer rare
IX	Native American Indian and Native Alaskan	There are over 70 Native American tribes and 8 Alaskan races *See attached list.	Medium Olive tones. Red undertones.	Rarely burns, tans well, high sun tolerance. Skin has a tendency to turn leathery with age and excessive sun exposure. Pigmentation	Environmental Damaged Excessive phot damage Hyperpigment / Melasma Ski

				changes may occur. Thick dark scarring. Normal oily skin.	Cancer rare
X	Black or African American	Eastern Africa, Middle Africa, Northem Africa, Southern Africa, Westem Africa, The Carribbean. *See attached list.	Medium-Dark Brown Tones.	Never burns with sun exposure, tans well. Pigmentation issues common. Very little fine wrinking. Formation fo Keloids possible. Oily skin.	Hyperpigment Melasma Acne Prone Post inflammatory Hyperpigment Pseudo follicul Skin Cancer ve rare
XI	Mix of two or more races	Any combination	Varies depending on race combination.	Take the predominant traits into consideration.	Treat with cau Use milder programs to st graduating to stronger produ absence of irritation.

METHODOLOGY IN WHICH THE STUDY WAS CONDUCTED:

The research was carried out at Skin Rejuvenation Clinic in San Francisco during 1997–2005. All subjects were residents of USA; a total of 588 subjects, both female and male (majority female) were chosen; they were of different races.

Charts and records were followed during this period to gather the information for the study. All data were manually collected through these charts and records collected from each individual client visit. The initial consultation is where the data were collected from the client. The minimum treatment process was eight visits over a four-month period, two visits a month. Thereafter monthly maintenance visits.

During the initial visit a client filled out a three-page Skin Evaluation questionnaire that asked several questions pertaining to several different factors, which included:

Skin Evaluation	
Skin Type	
[ ] Very Dry	Dry all over—all the time, tight, easily irritated, sensitive
[ ] Dry/Mature	Mostly dry, tight, maturing/aging, sun/photo-damaged, loss of tone
[ ] Normal to Dry	Normal in the T-zone, dry on the sides of face
[ ] Normal	Slightly oily on the T-zone, normal on the sides of face
[ ] Normal to Oily	Oily in the T-Zone, slightly oily on sides of the face
[ ] Oily	Very oily in the T-Zone, slightly oily on the sides of the face
[ ] Very Oily	Very oily all over, all the time, prone to breakouts and acne
[ ] Blemished	Oily with tendency to active acne or acne-prone skin

History/Pigmentation Country of origin and ancestral race

What is your ancestry? Parents:_____ Grandparents

Pigmentation (How do you tan?)

How do you tan? [ ] *Burn [ ] Usually Burn [ ] Burn then Tan [ ] Usually Tan [ ] Always Tan* Pigmentation tendencies: [ ] Even [ ] Uneven [ ] Hyperpigmented [ ] Melasma **Vascularity** *Broken capillaries: [ ] Nose area [ ] Cheek area [ ] Chin area [ ] Forehead*

[ ] Entire face

Acne *Do you have a history of any of the following?*

[ ] Acne [ ] Whiteheads [ ] Blackheads [ ] Pimples [ ] Enlarges Pores
[ ] Flakiness [ ] Scars [ ] Erythema [ ] Post-Inflammatory Hyperpigmentation
[ ] Pits [ ] Cysts

Sun Exposure/Environment Do you spend time in the sun?

[ ] Seldom [ ] Occasionally [ ] Frequently Approximately how many hours do you spend in the sun a week?

Do you use a sunscreen on a daily basis? _____ What SPF? [ ] 15 [ ] 30 [ ] 30+

At what age did you start to use a sun block on a regular basis?

What percentage of time do you spend in the sun?

Summer _____ Winter

Where did you reside the first 20 years of your life?

Country _____ Region/City

Please note that most damage is accumulated during the first 18 years of your life.

Have you actively sunbathed in the past? [ ] Yes [ ] No Do you currently sunbathe? [ ] Yes [ ] No Do you use tanning beds? [ ] Yes [ ] No Have you ever had skin cancer? [ ] Yes [ ] No Do you have a family history of skin cancer? [ ] Yes [ ] No Relationship _____

Free Radical Exposure Do you smoke? [ ] Yes [ ] No How much? _____

Do you consume alcohol? [ ] Yes [ ] No How much? _____

Do you have a healthy diet? [ ] Yes [ ] No Do you exercise on a regular basis? [ ] Yes [ ] No Do you take vitamins? [ ] Yes [ ] No Which ones?_____

Lifestyle Sleeping habits [ ] Poor [ ] Good [ ] Minimal [ ] / 6 hours [ ] 7 hours [ ] 8 hours Stress level [ ] Minimal [ ] Moderate [ ] Excessive Do you meditate? [ ] Yes [ ] No How often? _____

Healing Ability Does your skin appear fragile and thin? [ ] Yes [ ] No Do you bruise easily? [ ] Yes [ ] No Do you scar from cuts or burns? [ ] Yes [ ] No Do you have a tendency to keloid? [ ] Yes [ ] No Have you had a deep

peel? [ ] Yes [ ] No Did you heal well? _____

Do you have facial laser treatments? [ ] Yes [ ] No When the skin evaluation was completed, the skin was further categorized and documented by complexion and skin characteristics of various skin types from different genetic backgrounds.

Complexion/ Skin Characteristics ***Skin Characteristics of people with Anglo-Saxon origins*** **Fair, dry thin-skinned**

Scars heal well

Signs of aging appear earlier

Burn easily in the sun

Bruising more obvious

Greater chance of skin cancer

Skin Characteristics of people with Southern Mediterranean origins Oily, olive-dark complexion

Signs of aging appear later

Cartilage tends to droop

Darker, thicker scars more common

Wrinkles appear later and in more localized areas Skin cancer rare

Skin Characteristics of people with Northern European origins / German and Scandinavian Fair, blue-eyed, blonde

Thin skin

Scars heal well

Signs of aging appear early

Bruising more obvious

Greater chance of skin cancer

Skin Characteristics of people with Southern European origins Dark, oily brunette complexion

Signs of aging appear later

Fine wrinkling less common

Bruising lasts longer

Scars may be thicker and darker

Skin cancers less common

Skin Characteristics of people with Northern European/Irish and Northern England Ruddy freckled complexion

Red hair
Scars usually thin
Signs of aging appear later
Bruises easily
Pigmentation problems
Skin cancers most common in this type

Skin Characteristics of people with African origins Signs of aging appear very late
Very little fine wrinkling
Formation of keloids is possible
Pigmentation changes may occur
Thicker cartilage hard to change
Skin cancers very rare

Genetically, this skin type is less susceptible to damage from UV radiation, although the skin can still get burned.

Skin Characteristics of people with Asian origins Signs of aging appear late
Fine wrinkling does not usually occur
Pigmentation changes may occur
Eyelid surgery more difficult
Skin cancers very rare

The completed questionnaire was then evaluated and categorized according to primary skin condition to be treated and the secondary skin condition to be treated. A woods lamp was used during the initial consultation to further check for photo-damaged, congested skin, hyperpigmentation/melasma This data collected gave further clarity to the client's skin type.

A UV photo was taken through the canfield polarized camera; this visually showed the UV photo damage and was documented.

3.2.3 SUMMARY, ANALYSIS

During the years of 2005 and 2011 the collected data were reviewed and the conclusions were as follows:

- Subjects from a similar geographical region or ancestral region (country of origin) had similar skin types and characteristics.
- Common skin conditions were similar.
- Complexions had similar undertones according to region (lighter complexions in northern cooler climates and darker around the equator where it's the hottest). Undertones of Asian countries were yellow/olive and undertones of Europe more ruddy, red/pink.
- Migration to another country did not change the original skin type or characteristic.
- There were many mixed races that had combined skin types.

3.2.4 WHERE METHODOLOGY MEETS RESULTS

The method in which the data were collected and notes taken during office visits showed that skin from similar races or country of origin had similar skin types and skin characteristics.

Upon completion of the review of skin evaluation data, the skin type section of the EP Global Skin Classification was based on the collective findings of skin type, with sun exposure, environment, and lifestyle data combined.

The compiled data were then assembled into an organized chart, hence creating the **EP Global Skin Classification Scale**. (Refer to Figure 1.)

3.2.2.1 INTRODUCTION

Skin of color is sometimes referred to as pigmented or ethnic skin. It simply means having enough pigment in the skin to impart a color other than white. In general, people of African, Asian, Latin, Native American, Pacific Islander, or mixed racial origins are considered to have skin of color. The demography of the United States is predicted to shift dramatically to the point where the majority of the population will fall under this category by 2050.[1]

There are several dermatologic diseases that are more commonly encountered in this population. In particular, disorders of pigmentation such as melasma and

post-inflammatory hyperpigmentation are among the top skin concerns to prompt a visit to the dermatologist.[2]

3.2.2.2 SKIN PHOTOTYPES

The Fitzpatrick classification of skin types (Table 1) is based on an individual's ability to tan and propensity to sunburn. The skin photoype is generally correlated with degree of pigmentation. For example, Type I skin is typically seen in people of Celtic origin whereas Type VI skin is mainly seen in people of Sub-Saharan African ancestry.

Table 1: Fitzpatrick Skin Types

Skin type	Skin color	Sunburn and tanning history
I	White	Always burns, never tans
II	White	Always burns, tans minimally
III	White	Burns moderately, tans gradually
IV	Olive	Minimal burning, tans well
V	Brown	Rarely burns, tans darkly
VI	Dark brown	Never burns, tans darkly black

a. Melasma

Melasma is an acquired patchy hyperpigmentation predominantly occurring in individuals with Fitzpatrick skin phototypes III and IV. It is a common disorder affecting nearly 5 million people in the U.S. alone. Although most frequently seen in women, 10% of cases occur in men. The reported prevalence ranges from 8.8% of Hispanic women in the Southern U.S. to 40% of Southeast Asian females.[3]

Melasma occurs primarily in 3 clinical patterns: 1.) centrofacial, 2.) malar, and

3.) mandibular, although many patients have a mixture of these presentations (Figure 1). The most common is centrofacial and consists of light to dark brown patches occurring on the forehead, cheeks, nose, upper lip, or chin. The malar pattern affects the cheeks and nose, while the mandibular pattern occurs along the jawline.

Figure 1 Melasma The clinical manifestations of melasma are thought to result from the presence of biologically hyperactive melanocytes in the affected skin. The exact etiology of melasma remains unknown, however, several risk factors have been identified. Affected individuals frequently have a family history suggesting the influence of genetics.

In addition, sun exposure is a common exacerbating factor most likely through upregulation of melanocyte-stimulating factors. The high incidence of melasma in women, especially those who are pregnant or taking oral contraceptives, suggests an important role for estrogen.

The location of excess pigment, which can be assessed using a Wood's lamp, tends to correlate with the response to therapy. In general, involvement of the more superficial epidermis is more amenable to treatment than that of the deeper dermis.

A critical component in the treatment of disorders of hyperpigmentation is sun protection. This is most commonly achieved by wearing sun-protective clothing and a broad-spectrum sunblock. Without these measures, any treatment regimen is bound to fail. Hydroquinone 4% cream is FDA-approved for the treatment of hyperpigmentation and considered by many to be the gold standard. This medication works by inhibiting the melanin-producing enzyme known as tyrosinase. Sometimes higher concentrations are needed which must be compounded by a pharmacy. The addition of tretinoin cream may enhance

efficacy. Non-FDA approved natural alternatives to hydroquinone include kojic acid, arbutin, soy, licorice extract, rucinol, mulberry, niacinamide, ellagic acid, resveratrol, and dioic acid. Other methods of treating hyperpigmentation include laser therapy and chemical peels.[4]

b. Post-inflammatory Hyperpigmentation

An increase in pigment occurring after an inflammatory event is known as post-inflammatory hyperpigmentation (PIH). This cosmetically distressful phenomenon is extremely common in people with skin of color. Frequent causes of PIH include acne, eczema, psoriasis, burns, and certain cosmetic procedures. It is of utmost importance that the underlying cause of PIH be addressed if still present. The treatment of PIH is otherwise similar to that of melasma.

c. Vitiligo

Vitiligo is an acquired disorder of depigmentation estimated to affect 0.5% to 1% of the population.[5] Although vitiligo can occur at any age, almost half present before age 20. Both sexes are affected equally and there is no difference in rates of occurrence according to skin type or race. It can be a psychologically devastating, particularly in people with darker skin, because it is more noticeable.

Vitiligo is divided into three types: localized, generalized, and universal. The generalized type is most common, resulting in widespread symmetric white macules and patches. Areas of predilection include the fingers and wrists, axillae and groin, and body orifices, such as the mouth, eyes, and genitals. There is a propensity for lesions to occur in sites of trauma, which is a process known as koebnerization. The universal type is defined as having at least 80% skin involvement (Figure 2).[5] Lesions begin insidiously and are generally slowly progressive either by centrifugal expansion of current lesions and/or the appearance of new lesions. Spontaneous repigmentation occurs in no more than 15% to 25% of cases.

Figure 2 Extensive facial depigmentation occurring in a patient with vitiligo

Under the microscope, vitiligo is characterized by the absence of melanocytes. The exact reason behind their disappearance is unclear but several theories regarding autoimmune, genetic, oxidative stress, and neural mechanisms have been proposed. Currently, the evidence is most strongly suggestive of an autoimmune process occurring in genetically predisposed persons. Indeed, nearly 20% of people with vitiligo have at least one first-degree relative also affected by the disease.[5] Vitiligo may also be associated with other autoimmune diseases such as Addison's disease, pernicious anemia, diabetes mellitus, thyroid disease, and alopecia areata.

The treatment of vitiligo can be a frustrating process. Numerous treatment options exist but a cure remains elusive. As such, goals for treatment include halting disease progression, inducing repigmentation, and achieving an acceptable cosmetic result. It is also important to address the psychosocial impact of the disease. In general, the response to treatment is often slow and may be modest at best.

Current treatment options include topical and systemic steroids, topical calcineurin inhibitors, topical Vitamin D3 analogs, narrow-band UVB phototherapy, and excimer laser. Among these, the gold standard and most frequently used treatment is narrow-band UVB phototherapy.

Surgical therapy may be an option for people with focal non-progressive vitiligo who have failed phototherapy. Total depigmentation with monobenzone is a last resort reserved for individuals with extensive recalcitrant vitiligo who desire a uniform skin color. Cosmetic camouflage may be helpful in concealing areas of vitiligo occurring in particularly noticeable areas such as the face and neck.

d. Idiopathic Guttate Hypomelanosis

Idiopathic guttate hypomelanosis is a common disorder affecting nearly 80% of people over age 70. Although it occurs in all races and skin types, it is more noticeable in darker skinned individuals. It presents as several, well-defined, hypopigmented 1-6 mm flat spots with a smooth surface on the forearms and shins. The etiology is unknown but sun exposure is thought to play a role. Treatment with liquid nitrogen may be beneficial but must be weighed against the risk of causing post-inflammatory hyper-or hypopigmentation in darkly pigmented skin.

e. Pseudofolliculitis Barbae

Pseudofolliculitis barbae (PFB) is otherwise known as razor bumps or ingrown hairs. The disorder is associated with shaving and is particularly common in the beard area of black men or groin area in women. It is caused by newly shaved tightly curled hairs curving back into and piercing the skin, which results in an inflammatory reaction. PFB presents clinically as inflamed bumps and pustules, which may result in post-inflammatory hyperpigmentation and keloids.

The ideal treatment is to completely stop shaving and instead use a trimmer to leave 1-2mm of stubble. If this is not feasible for personal or professional reasons, a low potency topical steroid and topical antibiotic may be used to reduce inflammation. Other options for treatment include chemical depilatories, laser hair removal, and eflornithine cream.

CONCLUSION

The study of ethnic skin is absolutely necessary to meet the demands of our shifting demographics. Tremendous progress has been made in terms of understanding the biological mechanisms behind disorders of pigmentation. This, in turn, should spur the innovation of more effective medications and cosmeceuticals.

ABSTRACT

The darkening of skin color in larger segments of the world's population is an emerging trend according to numerous projections. Concomitant with this change is that new, specific skin care needs are an emerging opportunity for product development in these growing markets. To serve these needs, professionals have to be abreast of the needs of this new and growing sector and they must understand this diverse global consumer. This chapter focuses on Asian ethnic skin, which is a new category as defined elsewhere in this book and known as EP V-VII in the EP Global Skin Classification Scale.

By 2014, skin care will increase its already-sizeable lead in the beauty market

to reach $91 billion (*Euromonitor International*). This increase is driven primarily by expansion of opportunities in the Asian market. Even in USA the Asian population grew faster than any other major race group between 2000 and 2010, increasing by 43% (U.S. Census Bureau).

By 2050, the U.S. population projections are that 51% of Americans will have skin of olive tones and dark-skinned racial backgrounds (Hispanics, Black, Asian, others) according to the PEW Research Center.

The most apparent difference in the skin of those from different ethnicities is, of course, the color, although there are also differences in skin thickness, vascularity, and predispositions to certain skin conditions and diseases. Pigmentation disorders are a primary concern for Asian ethnic skin as well as a tendency for acne for those with normal to oily skin.

The ingredients and methodology applied in creating effective corrective cosmeceuticals for this segment of the population must take these ethnic skin differences into account. Multiple symptoms and conditions, such as hyperpigmentation with oily skin, can then be treated with today's sophisticated formulations.

Market research shows that consumers are streamlining the number of products they buy and focusing on products that are targeted to correct more than one condition. It is therefore important for industry professionals to focus on development of "necessity products" in these skin care ranges.

3.2.3.1 Defining the Asian Ethnic Market

3.2.3.2 Differences Between Content Levels of Melanin in the Skin

3.2.3.3 Common Skin Conditions for Ethnic Skin and Treatment Methods

3.2.3.4 Tips to Achieve Healthy, Beautiful Skin

INTRODUCTION:

In modern-day India, a woman's worth is all too often determined by the color of her skin. In India, beauty lies not only in the eyes of the beholder but in societal pressure to be fair-skinned. Arranged marriages are still popular and mothers seek fair-skinned brides for their sons; in fact everyone seeks such brides/grooms. Being dark is undesirable and affects the marriage process; a

darker-complexionrf girl, even with beautiful features, is not considered beautiful. Billboards all over India promote fairness, and ads on TV promote fairness with success and beauty.

Culturally this applies to Indians living in foreign countries as well: fair is considered beautiful. My personal experience in the west has been that Asians want lighter complexions and Caucasians want to be darker and tanned. It's like wanting what is not real. I feel we should all be happy with the complexion we are born with and not let societal or cultural pressure tell you otherwise. Taking care of your skin and bringing it back to optimum health by using good products is a necessity and no longer a luxury.

3.2.3.1 DEFINING THE ASIAN ETHNIC MARKET:

Pale skin has always been the ideal for women in Asian cultures for a long time. It has nothing at all to do with wanting to be more "white" in the racial or cultural sense. Up until the 1920s pale, unblemished skin for women was the ideal in western cultures as well. Browned skin was undesirable, since it was considered a trait of only the poor who endured hard labor outdoors. Well-off women used to apply all kinds of products to their skin to whiten them, and both Chinese and Japanese cultures have proverbs that imply "a white skin hides other flaws." Those sayings have existed for ages.

All across Asia, fair skin is highly prized. In dark-skinned South Asia, a fair complexion is considered the epitome of beauty while in already pale-skinned North and East Asia, pearly translucent white skin is a sign of affluence and glamour. In Asia, many people associate dark and tanned skin with menial work in the fields under the hot sun, and a pale complexion with a higher social standing and cultural refinement. Since the 1970s, Asia has been the fastest-growing sector in the global skin-lightening market. Asia is a lucrative market with high-growth potential because of a rising middle-class with increasing disposable income and centuries-old entrenched cultural impressions of beauty.

India's domestic cosmetics industry is expected to grow to US$3.6 billion by 2014, according to the Associated Chambers of Commerce and Industry of India. The skin-lightening cream market alone was worth US$432 million in 2010 and growing at 18% annually.

In Japan the cosmetics industry is growing at 17% a year and is expected to continue that rapid pace for a few more years at the very least, largely because of the hundreds of millions of emerging middle-class women who are spending

their money on cosmetics. (1)

In China, where the skin care market is worth more than 35 billion yuan (US$5.5 billion), whitening products comprise a whopping 71% of the market. Elsewhere in Asia, a survey by the London-based market research firm Synovate found that four out of ten women in Hong Kong, Malaysia, the Philippines, South Korea, and Taiwan use a skin-whitening cream.

The cosmetics industry has also started to target men, selling them the same idea that a fairer complexion would make them more attractive. While skin-lightening products for women have been available for decades, products for men have only appeared in recent years, a trend that is rapidly growing. (2)

Japan dominates the global skin lighteners market with the lion's share, as stated in the new market research report from Global Industry Analysts, Inc. (GIA). The market for skin lighteners in Asia-Pacific is projected to cross the $2 billion mark by 2012, driven by the fast-growing markets of China and India. Apart from Asia, Western countries such as the United States and the United Kingdom are emerging as potential markets for skin-whitening products. The growing proportion of ethnic groups—Asians, Hispanics, and African Americans—in these regions is a major contributor to the enhanced demand for skin lighteners.

In Asia, skin-whitening products are very popular. The West seems to believe that these products are made because Asians want to become more Western, which isn't true. Fair skin has been a staple in beauty for Asian cultures for centuries; even old paintings in Asian cultures portray women as fair with flawless complexions.

Western society's obsession with skin tanning is well recognized, but we're often less aware of the aggressive pursuit of fair skin by those with darker skin. In communities where light skin is associated with success, prestige, and envy, women commonly turn to skin-lightening products to achieve and maintain their desired complexion.

In India, the appeal of fair skin is deeply rooted in the nation's culture and the caste system. Higher caste members traditionally had lighter skin and were less likely to be involved in manual work. Many years later, the ruling colonials had fair skin. And in the last century, film, TV, and advertisements have been saturated with images of attractive western actresses with fair skin. Skin-lightening creams are reportedly the most popular product on the Indian skin care market, with around 60% of Indian women using the products daily.

Data as at May 11, 2011. Source: United Nations World Population Prospects, Haver. Size of bubble indicates 2012 population.

Global diversity continues to grow throughout the world as Asian ethnicity remains a constant that makes up the majority of the world's population. The need for an assortment of products that are relevant to the specific multicultural market continues to drive research and technology in the skin care industry. Although Asian ethnic skin care products exist, the market struggles to find skin care products that are optimal in addressing their particular needs. It's important for brands to connect with ethnic consumers and address specific concerns to a wide array of skin types. Women and men of color around the world experience very distinctive issues related to their skin types, and the amount of pigment varies significantly between many ethnic groups. As noted in the EP Global Skin Classification Scale, each region/race has its unique skin color, characteristics, and related skin conditions.

A. Mediterranean/Asian I (EP Global Skin Classification V)

Afghanistan, Albania, Algeria, Armenia, Azerbaijan, Bahrain, Iraq, Iran, Israel, Jordan, Kazakhstan, Kuwait, Kyrgyzstan, Lebanon, Oman, Palestine, Qatar, Saudi Arabia, Syria, Tajikistan, Turkmenistan, UAE, Uzbekistan, Yemen

B. Asian II (EP Global Skin Classification VI)

Brunei Darussalam, Cambodia, China, Hong Kong, Indonesia, Japan, Korea, Laos, Macao, Malaysia, Mongolia, Philippines, Singapore, Taiwan, Thailand, East Timor, Vietnam

In Asia, a lighter skin color is associated with beauty and aristocracy. Asians have skin properties that set them apart from Caucasians. They have more yellow undertones, and skin color ranges from fair to dark. Sometimes Asian skin types can be deceiving and not appear to have a high content of melanin, which is why taking each person's ethnicity into account is crucial. Asian skin

does in fact contain more pheomelanin pigments, which determines the yellow undertone skin color. Despite how Asians of different regions seem to sport different skin colors (Japanese are the fairest, with little redness in their skin; Indians are the darkest, with more skin redness), all actually have yellow undertones. Some might be stronger than others, like Asians of Malay origins (e.g., many Malaysians and Filipinos) have the most yellow "tones." Why yellow? It has to do with pheomelanin: high level of this type of melanin in the skin results in yellow undertones.

C. Asian III (EP Global Skin Classification VII)

Bangladesh, Bhutan, India, Maldives, Myanmar (Ex-Burma), Nepal, Pakistan, Sri-Lanka, Tibet

South Asians have a different skin type when compared to the Caucasians and require a different skin care schedule. Cosmetics used by Caucasians do not suit all Asian skin types. Asian skin is usually brownish, and skin tone varies according to the region of origin. Excessive melanin contributes to the brown color and also excessive melanin in the skin weaves a protection against skin cancer. In spite of excessive melanin content, South Asians are prone to pigmentation, age spots, freckles, *etc.* due to severe climatic conditions. Aging does not show up as wrinkles in South-Asians but rather as hyper pigmentation, dark spots, uneven skin tones, freckles, *etc.*

3.2.3.2 DIFFERENCES BETWEEN CONTENT LEVELS OF MELANIN IN THE SKIN

Differences between skin colors are determined by the amount of melanin produced by the melanocytes. Melanin comes in two different forms: pheomelanin, which gives the skin more red to yellow pigments, and eumelanin, which gives the skin dark brown to black pigment. The relative proportions of

these two types of melanin determine the skin color. For example, lighter skin types produce a lesser amount of melanin whereas darker skin types produce more melanin. Also, some Asian skin types might appear to be fairer with strong yellow undertones; therefore their skin contains higher levels of the pheomelanin pigment. No matter the amount of melanin produced, we all have the same number of melanocytes in our skin, which are the cells that produce melanin (pigment). In darker skin types the melanocytes are more sensitive to irritation and react more aggressively to injuries. An example of injury can be as simple as extracting a blackhead and applying too much pressure on the skin, which results in trauma to the skin where a dark spot is formed, also known as post-inflammatory hyperpigmentation. This is a common problem associated with those who contain more melanin in their skin. Hyperpigmentation occurs more often in those with darker skin, which can be a result from burns, inflammation, scraps, cuts, or even a pimple. Those who suffer with acne, eczema, and ingrown hairs will also result in uneven skin tone and hyperpigmented spots.

Another key point of difference in those with darker skin is the sebaceous glands that produce oil/sebum. These glands tend to produce higher levels of oil, which results in excessive oil production and ultimately results in overdrying the skin. A huge benefit for those with higher melanin content or more color in their skin is that they will tend to see signs of aging later on in life. Melanin acts as a protector for our skin and helps to ward off the UV rays of the sun by absorbing them, and keeping them from penetrating the skin. Whenever the skin detects excess solar radiation it produces more melanin and more melanin means darker skin, hence, the suntan. This not to say that people of color do not get wrinkles; it just means that aging takes place differently and the propensity for irritation and hyperpigmentation is magnified for their skin type. Therefore a greater knowledge is required for product choice and professional treatment options. Most commonly Caucasian women tend to seek out skin care products for anti-aging properties and moisturizing, whereas women with more color look for products to correct and prevent uneven skin tone and blemishes.

3.2.3.3 COMMON SKIN CONDITIONS FOR ETHNIC SKIN AND TREATMENT METHODS

With social media and companies paying attention to wanting to help the consumer solve a skin care problem, I feel that the time has come in the industry where companies can collaborate to help educate consumers on how important

prevention is and making lifestyle changes to support this. For example, if someone in their 30s wants to lighten their skin, it is mandatory that daily use of a SFP30 is also part of the regime. Direct sun avoidance during peak times is essential, and if not, a precaution such as a hat or additional protection measure should be taken.

With a collaborated campaign that is more educational, the message will reach out to consumers and change will happen. Social media plays a big role in that it can assist with getting the right message out to consumers, making it more fun and easier to grasp. In most Asian countries TV and media still play a big role in the lives of the masses, so some form of education via this method may also be very effective. Along with more education will come better preventative steps which will essential be the most successful approach to reduce dark spots.

Prevention is a key to successfully reducing the risk of hyperpigmentation in the future. A good skin care regimen followed a.m. and p.m. will help provide preventative results. A preventative regimen must include some type of mechanical or chemical exfoliation three times a week, a melanin-suppression formula, and sunscreen. The first step is to exfoliate the skin so that the dead skin cells are removed and to reveal brighter skin tone. Exfoliation will help increase the cellular turnover, so results are seen more quickly from the skin-brightening product. The second step is to use a skin-brightening product twice a day after cleansing the skin. There are a variety of skin-lightening products on the market, so the best thing to look for is the product containing the most amount of skin-lightening active ingredients. Some formulas contain hydroquinone and others do not. There are many alternatives in the market to address different skin types and pigment disorders. Refer to the list of skin-lightening actives. The last step will be to protect the skin from the harmful UV rays. Sun is the number one precursor to pigment formation. Protecting the skin with a broad-spectrum SPF of 30 will provide the best protection from UV-A and UV-B rays. If exposed to the sun for a long period of time reapply sunscreen every two hours for adequate protection. Below are common skin conditions and different causes and treatments.

Melasma (also known as chloasma or “pregnancy mask”) is a common skin condition. It causes brown to gray patches of discoloration, very common in women during the reproductive years. Melasma is dark, irregular, well-demarcated hyperpigmented macules/patches commonly found on the upper cheek, nose, upper lip, and forehead. It can also appear on parts of the body that get excessive sun exposure such as forearms and neck and décolleté area.

Causes of Melasma: Hormonal changes in the body, genetics, and overexposure to sun. History of excessive or intermittent sun exposure. Pregnancy, birth control pills, HRT, other medications (diuretics, antibiotics, heart disease, diabetic, hypertension meds). Products or treatments that irritate the skin may cause an increase in melanin production and accelerate melasma symptoms.

People with olive or darker skin, like Hispanic, Asian, and Middle Eastern individuals, have higher incidences of melasma. People with a genetic predisposition or known family history of melasma are at an increased risk of developing melasma. Important prevention methods for these individuals include sun avoidance and application of extra sunblock to avoid stimulating pigment production.

An estimated 6 million women are living in the U.S. with melasma and 45–50 million women worldwide live with melasma; over 90% of all cases are women. Prevention is primarily aimed at facial sun protection and sun avoidance. Treatment requires regular UVA & UVB sunblock SPF 30 application and skin-lightening, -whitening and -brightening creams. (3)

Treatments for Melasma:

Microdermabrasion: utilizes vacuum suction and an abrasive material like fine diamond chips or aluminum oxide crystals to exfoliate the top layers of the skin. The vacuum pressure is adjusted depending on the sensitivity and tolerance of the skin. Typical microdermabrasion sessions can last anywhere from a few minutes to one hour. Minimal to no recovery time is needed after microdermabrasion. Microdermabrasion techniques can improve melasma, but dramatic results are not generally seen or expected after one or two treatments. Multiple treatments in combination with sunscreen and other creams yield best results.

Chemical peels: Many types and strengths of chemical peels are available for different skin types. The type of peel should be tailored for each individual and selected by a physician.

TCA: TCA peels are excellent and safe in the hands of an experienced dermatologist. This is a good option, particularly if you have severe melasma.

AHA +combinations: In treating melasma, 30–70% glycolic acid peels are very common. Various combination peels, including a mix of glycolic acid, kojic acid, lactic acid, etc., can be used to treat melasma. Usually six sittings at a gap of ten days produce good results.

Ultrasonic: Treatments with whitening jelly can be used in conjunction with chemical peels or MDA to further enhance results.

IPL treatments with pigmentation filter or currently Fractional Laser Treatments are being used to reduce pigmentation. Usually three to four treatments are needed at a gap of 15–20 days.

Although melasma tends to be a chronic disorder with periodic ups and downs, the prognosis for most cases is good. Just as melasma develops slowly, clearance also tends to be slow. The gradual disappearance of dark spots is based on establishing the right treatment combination for each individual skin type. Melasma that does not successfully respond to treatment is because sun exposure is not avoided.

Peri-Orbital Hypermelanosis (Undereye dark circles): This is a very common disorder among the Asian population, especially the Indian population. Undereye circles, which are dark pigments around the peri-orbital area, may be hereditary, or due to stress or eye strain. Also, those suffering from allergies seem to have dark circles. Smoking, drinking a lot of alcohol, coffee, soda, or caffeine beverages will usually make dark circles worse. Diet also plays a role and not having a healthy diet can affect it as well. A lack of sleep is a big culprit, so pulling all-nighters—whether for school or fun—can also contribute to dark circles around the eyes.

Treatments of Peri-Orbital Hypermelanosis: Once the cause has been identified there are several available solutions for treatment of this common disorder. Using a good eye cream that has ingredients specifically targeted to this delicate area, twice a day, will help prevent moisture loss, hydrate the area, and assist the delicate skin in absorbing the moisture and active ingredients, while stimulating the blood supply. Also wearing sunglasses can help prevent further pigmentation when exposed to the sun.

Photomelanosis: This is increased pigmentation due to sun exposure; it is also known as sun damage or photo-damage. The pigmentation occurs on exposed skin, commonly on the face, neck, and back. The pigmentation may be patchy or a diffused darkening of the exposed skin.

Hyperpigmentation: Hyperpigmentation is the production of excess melanin causing dark spots on the skin. Age spots, liver spots, freckles, sun spots, and pregnancy mask are all types of hyperpigmentation.

Causes of Hyperpigmentation: Common causes of skin hyperpigmentation are excessive sun exposure, hormonal changes, heredity, acne, and irritations

from skin treatments and products. Hyperpigmentation may also be caused by inflammation, or by other skin injuries, including those related to acne vulgaris. In situations where hyperpigmentation is caused by acne or some other cause of skin inflammation, it is known as PIH, or post-inflammatory hyperpigmentation. People with darker Asian, Mediterranean, or African skin tones are also more prone to hyperpigmentation, especially if they have excess sun exposure.

Many forms of hyperpigmentation are caused by an excess production of melanin. Hyperpigmentation can be diffuse or focal, affecting such areas as the face and the back of the hands. Melanin is produced by melanocytes at the lower layer of the epidermis. Melanin is a class of pigment responsible for producing color in the body in places such as the eyes, skin, and hair. As the body ages, melanocyte distribution becomes less diffuse and its regulation less controlled by the body. UV light stimulates melanocyte activity, and where concentrations of the cells are denser than surrounding areas, hyperpigmentation is affected. It can also be caused by using skin-lightening lotions. (4)

Post-Inflammatory Hyperpigmentation: a very common condition for those with more color in their skin. Many types of trauma, inflammation, medications, cosmetics containing alcohol or fragrance, and skin conditions including: acne, eczema, contact dermatitis. Systemic disease such as Addison disease, liver disease, pregnancy, and pituitary tumors can also cause hyperpigmentation.

Acne Vulgaris: one of the biggest challenges to women with brown skin who seek clear, glowing complexions. In addition to the acne, women with brown skin must also face hyperpigmentation—skin darkening in spots or patches—which occurs in response to the acne outbreak.

Acne Rosacea: not one of the skin problems typically associated with skin of color. A main feature of rosacea is redness or erythema of the face. But rosacea does occur in people of color, including African Americans, Latinos, and Asians, and is often undiagnosed or misdiagnosed.

Eczema: one of the more common skin problems for individuals with brown skin, including those of Asian, Latino, and African descent. It is felt to be the second-most-common skin disease in African Americans. Although it is unknown if the incidence of eczema is increased in Latinos, one study found a significantly higher percent of Mexican American adolescents with eczema than white and

African American adolescents.

Keloids: Abnormal healing of the skin occurs frequently in individuals with brown skin. When skin is injured, it may heal with one of several types of scars (keloids): normal (level with the surrounding skin), atrophic (depressed), hypertrophic (slightly raised), and keloidal (large and raised).

Seborrheic Dermatitis: often referred to as dandruff, is a common problem for many women with brown skin. Areas of involvement are the hairline and scalp, as well as the eyebrows, the area between the nose and corners of the mouth (nasolabial folds) and the ears.

Skin Cancer: People with brown skin often have a false sense of security when it comes to skin cancer. While individuals with increased skin pigmentation have added protection against the UV rays of the sun, it is dangerous to assume that darker skin exempts one from this serious skin problem.

Hypopigmentation: Areas of the skin that have lost their pigment completely when there are no longer functioning melanocytes in that area to create pigment, leaving white spots or patches on the skin. Hypopigmentation can result from overbleaching, or extensive trauma from UV light, lasers, or heat. Examples of hypopigmentation include:

Vitiligo: Vitiligo causes smooth, white patches on the skin. In some people, these patches can appear all over the body. It is an autoimmune disorder in which the pigment-producing cells are damaged. There is no cure for vitiligo, but there are several treatments, including cosmetic cover-ups, corticosteroid creams, or ultraviolet light treatments.

Albinism: Albinism is a rare inherited disorder caused by the absence of an enzyme that produces melanin. This results in a complete lack of pigmentation in skin, hair, or eyes. Albinos have an abnormal gene that restricts the body from producing melanin. There is no cure for albinism. People with albinism should use a sunscreen at all times because they are much more likely to get sun damage and skin cancer. This disorder can occur in any race, but is most common among whites.

Pigmentation loss as a result of skin damage: If you’ve had a skin infection, blisters, burns, or other trauma to your skin, you may have a loss of pigmentation in the affected area. The good news with this type of pigment loss is that it’s frequently not permanent, but it may take a long time to repigment. Cosmetics can be used to cover the area, while the body regenerates the pigment.

(5)

3.2.3.4 TIPS TO ACHIEVE HEALTHY, BEAUTIFUL SKIN

- Mandatory daily use of broad-spectrum UVA & UVB Sunblock – SPF30+
- Wash skin daily with mild nonsurfactant cleanser, use a clean towel to pat dry, do *not* rub the face harshly, or share towels with others. The face should be washed twice, both morning and evening.
- Drink water—an average adult typically needs 10–12 eight-ounce glasses a day. I prefer to drink room-temperature or hot water with a slice of lemon.
- Use quality skin care products that hydrate and repair the skin, and avoid products that clog your pores.
- Use lightweight facial makeup foundation or powders; this will allow the skin to breathe and prevent further breakouts. Personally I feel the less used the better; if you take care of your skin you will have a natural radiance.
- The skin is a very sensitive organ and given the level of abuse it goes through, is remarkably resilient. However, this resilience decreases as we age, and opens the door for bacteria, viruses, microbes, parasites, *etc.* that invade the skin. In climates such as Asia where it is hot and polluted, especially in the cities, environmental damage also plays a role in the aging process.
- If you have a tendency to break out, seek professional help to treat it and go for the root cause of the blemish, rather than using makeup to cover skin blemishes and trauma. This can save you permanent damage with scars and or ice-pick marks.
- Avoid skin trauma like tattoos, body piercing, *etc*. These abuses can age the skin, and expose it to bacteria and other viruses.
- When you notice skin discomfort, dryness, itchiness, reddening, discoloration, blemishes, lesions, bruising, tags, moles, bumps, warts, corns, calluses, or other skin trauma, seek professional help, as some conditions may get worse over time if not treated.
- Diet plays a crucial part in skin health, so eat wisely. Your diet should contain plenty of green leafy vegetables. Eat seasonal fruits and add nuts to your diet; if you have health issues it is wise to seek a nutritionist, or dietician, to establish a healthy diet to suit your unique skin and bodily needs.
- Make regular monthly visits with a skin care professional to help maintain

healthy skin. Having topical treatments such as Lactic Peels, chemical peels, microdermabrasion, and laser therapy specific for Asian skin.

- Treat yourself to regular spa treatments; having a regular full-body massage is not only relaxing but good for you too. A deep massage is good to maintain healthy skin, since the kneading breaks up old fat deposits and releases toxins. The sauna and steam bath are recommended to help keep skin moist, supple, healthy, and toned. Drink water to hydrate before and after your sessions.
- Minimize exposure to tanning machines, lamps, beds, *etc.* The tanning process is actually a form of skin abuse, and can result in premature aging of the skin and promote hyperpigmentation.
- Always use high-quality and well-made skin care products. Using a daily program that consists of cleanser, exfoliator, moisturizer, and SPF 30 is highly recommended. The reward is to enjoy clear, healthy, blemish-free, radiant, glowing, beautiful skin for many years.
- Avoid cheaply made skin creams with a lot of chemicals. Products that are highly fragranced, with artificial colors, binders, emulsifiers, etc., can cause some people to develop allergies, leading to rashes and pigmentation issues.
- In order to maintain healthy skin and overall health, a total avoidance of alcohol, tobacco, and illegal drugs is advisable. These are all toxic to the body and after many years of such abuse, the skin can become wrinkled, saggy, dry, and itchy, and can lose its suppleness. Reducing or eliminating caffeine, sugar, and soft drinks will also benefit the skin and overall health.

ABSTRACT

This chapter provides a thorough look at the structure and chemistry of the skin. It draws upon, and consolidates, the enormous body of literature on the subject and brings it together to form a solid foundation for the reader's understanding of skin aging as well as describing treatments of aging skin with selected effective "cosmeceuticals." We live in a culture that values a youthful appearance at a time when the population is aging rapidly in developed countries. According to the United States census there were ~57 million Americans age 60 and older in 2010, nearly a 25% increase in the ten years since the 2000 census. As people live longer, populations in Western Europe and Japan are also aging.

It is well known that the appearance of the skin can have dramatic effects on the overall impression of age. Both wrinkles (1, 2) and inhomogeneity of skin color (3–6) contribute significantly to the apparent age of individuals. The combination of the effect of skin appearance on apparent age and an aging population with the desire to look youthful has, not surprisingly, led to enormous interest in products that might make skin appear more youthful.

Skin aging is often broken into two categories referred to as intrinsic aging and extrinsic aging (7–9). *Intrinsic aging is the unavoidable effect of time.* It occurs on all body sites and is considered to be independent of lifestyle. Extrinsic aging results from lifestyle choices. The main factor is photoaging brought about by exposure to ultraviolet (UV) light from the sun (7, 10–12). While sun exposure is considered the main extrinsic factor leading to skin damage, it is becoming increasingly clear that exposure to cigarette smoke can lead to significant skin compromise both in smokers(13–21) and in nonsmoking spouses of smokers (22).

This chapter reviews the consequences of both intrinsic and extrinsic skin aging. Mechanisms underlying photoaging will be discussed, as will attempts to improve aging skin and at least partially reverse the effects of time and extrinsic insults.

TABLE OF CONTENTS

3.2.4.1 Structure of the Skin
3.2.4.2 Skin Aging: Changes in the Epidermis and Stratum Corneum
3.2.4.3 Aging and the Dermis

3.2.4.1 STRUCTURE OF THE SKIN

We begin with a brief review of skin structure to facilitate our discussion of skin aging. This subject is discussed in more detail in other chapters to this book. Discussion of the structure of skin will naturally refer to its various layers (23, 24) or strata. The skin's multiple layers work together to perform its multiple functions. Figure 1 is a hematoxyln and eosin (H&E) stained image of a cross-section of human skin.

Figure 1 (H&E stained cross section of human skin labeled to show the various layers. The "basket weave" appearance of the *stratum corneum* is an artifact of processing. http://en.wikipedia.org/wiki/Epidermis_(skin) public domain image)

The epidermis and dermis are fundamentally different types of tissue. The epidermis overlays the papillary dermis and is composed of cells. The main type of cell of the epidermis is the **keratinocyte**. Keratinocytes are found from the basal layer to the granular layer where they are transformed into the corneocytes of the *stratum corneum* (SC). Keratinocytes make many proteins including keratins, the main structural proteins of the SC (25). Two other important cells in the epidermis are melanocytes and Langerhans cells.

The **dermis** has two layers, papillary and reticular. The hypodermis or subcutaneous tissue is sometimes considered part of the dermis but will not be considered in this review. The dermis is a fibrous tissue composed primarily of collagen, elastin, and proteoglycans, which form the dermal matrix. The papillary dermis is named for the dermal papilla protruding into the epidermis (Figure 1). The fibroblasts, which make the proteins and proteoglycans of the dermis, are found in the dermal matrix (24).

The main structural protein of the dermis is collagen. Collagen has a unique amino acid sequence. Every third amino acid is glycine, which does not have a side chain. This allows collagen to form a compact triple-helix with three collagen chains winding around each other as if in a braid. Each triple helix is about 300 nm long and 1.5 nm in diameter (26). Collagen is synthesized in fibroblasts as procollagen and exported from the cell into the dermal matrix where it is processed by proteolytic enzymes, which remove sections from both ends of procollagen to form 300-nm filaments. These filaments then aggregate in the extracellular space to form collagen fibers.

The matrix in the papillary dermis is loosely packed with fibers compared to the tightly packed reticular dermis (24). The papillary dermis contains type III

collagen, which is found at relatively low levels in the reticular dermis where type I collagen predominates (27–29). Oxytalan fibers are thin (10–12nm) elastic fibers found perpendicular to the dermal-epidermal junction in the papillary dermis (30, 31). Elaunin fibers are also found in the papillary dermis parallel to the plane of the skin (30).

Elastin provides elasticity to skin (32). In elastin, four protein chains are bound together through the desmosine cross-link. Elastin has an amino acid residue called allysine, made from lysine by the enzyme lysyl oxidase. The desmosine cross-link is formed between three allylisine chains and one lysine chain. Amorphous elastin fibers surrounded by fibrillin microfibrils are found predominately in the reticular dermis (33, 34) (Figure 2).

Figure 2: Electron micrograph of the reticular dermis showing collagen, elastin, a fibroblast, and a mast cell. (© Raymond Boissy, used with permission)

Glycosaminoglycans or GAGS bind water in the dermal matrix (35) keeping the dermis hydrated. Hyaluronic acid (HA), a major component of GAGS, is a very high molecular weight. GAGs such as chondroitin sulfate and keratan sulfate bind to core proteins to form proteoglycans. Proteins called link proteins bind proteoglycans to HA in a noncovalent proteoglycan complex that is very hygroscopic.

Figure 2 is an electron micrograph of the reticular dermis showing collagen and elastin fibers as well as a fibroblast and a mast cell. Mast cells contain histamine granules and release histamine in response to heat or irritants. The reticular dermis is much more densely packed with fibers than the papillary dermis.

The dermal matrix is significantly affected by both intrinsic and extrinsic aging as will be discussed below.

Skin barrier function resides primarily in the epidermis and barrier may be considered "*la raison d'être*" of the epidermis (36). Layers of the epidermis are shown schematically in Figure 3.

Figure 3: Diagram showing layers of the epidermis (illustration by Robin M. Wickett)

The epidermal barrier defends the body from water loss to the environment, absorption of noxious chemicals from the environment, and microbial infection. These defensive functions depend critically on the top layer, the *stratum corneum* (SC), and are thought to be integrated with SC formation and homeostasis (37, 38).

For 30 years the most common model used to organize thinking about the SC barrier has been the "bricks and mortar" model proposed by Elias (39). This model is based on the fact that corneocytes are surrounded by the extracellular lipids of the SC. Thus the corneocytes are modeled as bricks and the lipids as mortar. The model has proven useful for representing the phenomena associated with describing ingredient skin penetration. Moderately hydrophobic molecules are thought to penetrate the SC by diffusing through the lipid mortar, winding their way around the corneocytes bricks (40). Harding has described an updated version of the bricks-and-mortar model that includes the presence of the desmosomes that hold SC cells together prior to desquamation and the role of natural moisturizing factor in SC function (41). This model is illustrated in Figure 4.

Figure 4: Schematic of the "bricks and mortar" model for human *stratum corneum* illustrating the corneocyte "bricks," the intercellular lipid "mortar," and the desmosomes connecting the corneocytes. (M.O. Visscher, used with permission)

The "bricks and mortar" of the SC barrier are formed in the *stratum granulosum* (SG) (Figure 4) where keratinocytes are transformed to form the corneocytes "bricks" and lipids are released into the intercellular space to form the "mortar." The SG is named for the two types of granules that appear in the cells, keratohyalin granules (24) that are composed of protein and lamellar bodies that primarily contain lipids (42, 43).

A complex process occurs in the SG: the nucleus is digested, the cytoplasm disappears, and lipids are released into the intercellular space to form the mortar (39, 44, 45). The keratin intermediate filaments aggregate to form microfibrils (46, 47) inside the corneocytes (48, 49). aided by filaggrin from the keratohyalin granules.

Filaggrin is an acronym for filament-aggregating protein (50–53). Filaggrin contains a high level of positively charged amino acids, allowing it to interact with the negatively charged epidermal keratins (54). Filaggrin is then modified to come off the microfibrils, through conversion of the positively charged amino acid arginine to uncharged citruline by the enzyme peptidyl arginine deminase (PAD) (55, 56). After release from the microfibrils filaggrin is digested by proteolytic enzymes to produce the amino acid components of the natural moisturizing factor (NMF) of the *stratum corneum* (57–62).

NMF consists of lactate, amino acids from filaggrin breakdown, and pyrollidone carboxylic acid (PCA) formed from the amino acid glutamine (63–

65). These natural moisturizers are important to maintain proper hydration of the SC allowing it to be flexible and to desquamate properly (57, 66–69). Digestion of filaggrin to NMF is thought to happen in the mid-*stratum corneum* (70).

In the *stratum granulosum* (SG) the keratinocyte cell membrane is replaced by the corneocyte cell envelope, a very tough structure made of cross-linked protein with lipids covalently attached to its surface (71–75). The resulting corneocytes or squames (the bricks) are flat cells that tend to be in the shape of either a hexagon or pentagon. Corneocyte size and distribution have been investigated by several authors. A single corneocyte is about 25 μm on a side, with a surface area ranging from about 550 to 1300 μm^2 depending on age and body site (76–79), and a thickness of about 0.5–1.0 μm (80, 81). Rougier *et al.* (79) reported corneocyte surface area on most body sites investigated to range from 900 to 1100 μm^2 but to be as low as 500 μm^2 on the forehead. A negative correlation was found between corneocyte size and the penetration of benzoic acid through skin *in vivo*. The *stratum corneum* is 12–16 cell layers thick on most body sites, but it can vary from as little as nine cell layers on the forehead or eyelids to as much as 25 on the dorsum of the hand and 50 or more on the palms or the soles of the feet (82, 83).

The lipids that are released into the intercellular space as the SC forms are glucosyl ceramides, cholesterol, cholesterol esters, and long-chain fatty acids. In the intercellular space the glucosyl ceramides are converted to ceramides (84, 85). SC ceramides are polar lipids, but much less hydrophilic than the phospholipids of the original cell membrane. Figure 5 shows the structure of some of the main SC ceramides with both the original and new nomenclature that is used for them. Phospholipids from the keratinocytes of the viable layers are broken down by phospholipases (86–88) in the lower *stratum corneum*. After this extracellular processing, SC lipids spontaneously organize into multiple layers between the SC cells (89). This layered structure is critical to the barrier function of the skin.

Figure 5: Key ceramides of the SC barrier.

3.2.4.2 SKIN AGING: CHANGES IN THE EPIDERMIS AND *STRATUM CORNEUM*

A general trend for corneocytes to increase in surface area with age has been reported by several groups (77, 79, 90-93). The reported increase in surface area between young adults and adults over 55 ranges from 8 to 14% depending on body site and method of measurement. Figure 6 shows corneocyte size data from two different age groups reported by Grove *et al.* (91, 93).

Note the extreme variability in the data from the older age group compared to the narrower distribution in the younger group. The average size of corneocytes is increased in the older age group but there is considerable overlap between the two data sets.

Figure 6: Projected corneocyte surface area for two age ranges for men (●) and women (○). Reprinted from Grove *et al.* (93) with permission of the Society of Cosmetic Chemists.

While the “bricks” of the SC may increase in size with age, the “mortar” content is apparently decreasing. Imokawa *et al.* reported a gradual decrease in total SC ceramides with age (94). Rogers *et al.* reported progressive reductions in fatty acids, ceramides and cholesterol with age in subjects ranging in age from 21–60 years on the hands, legs, and face (95). The reduction in ceramide I (EOS) linolate was especially noteworthy.

SC barrier function is affected by both intrinsic and extrinsic aging (96), but it is relatively robust to both and changes are not always in the direction that one might expect. The most common and best-validated method for determining SC barrier function *in vivo* is by measurement of the passive diffusion of water through the skin by measuring the rate water evaporates from the surface of dry nonsweating skin. This parameter is known as transepidermal water loss (TEWL) (97–99).

Several groups have studied the effects of age on SC barrier function by measuring TEWL. Results have varied. Roskos and Guy (100) reported no correlation between baseline TEWL on the ventral forearm and age for subjects ranging in age from 20 to 90 years, and Marks *et al.* (101) did not see a significant correlation to age on the forearm with a similar age range, but a trend to *lower* TEWL was observed for subjects above 55. Rougier *et al.* found no significant change in TEWL on the upper outer arm in subjects ranging in age from 20 to 80 years (79). Kligman (102) reported that TEWL on both the forearm and lower legs averaged slightly *lower* for a group of individuals aged 66–81 compared to a 19–26 year old cohort. Leveque *et al.* (77) reported TEWL from the arm to be approximately constant from 25 to 65 years of age but to decline slightly between ages 65 and 75.

Wilhelm *et al.* (103) compared TEWL data from a young group (26.7±2.8 years) and an older group (70.5±13.8 years) on several body sites. TEWL was significantly *lower* from the older age group on all sites except the palm. Saijo *et al.* (104) measured TEWL from the dorsum of the hand and the dorsum of foot on children from one to five years of age, young adults from 21 to 34 years of age, and older adults ranging from 63 to 78 years of age. Aged individuals had the lowest TEWL values on both body sites. There was no difference in TEWL from the dorsum of the hand between children and young adults. Ghadially *et al.* (105) reported average TEWL of 4.43±0.16 g/(m^2-hr) for a group of six individuals over 80 compared to 6.41±0.93 g/(m^2-hr) for a group of 21 subjects under 30.

Schwindt *et al.* (106) found significantly lower TEWL on the backs of

subjects averaging 69.8 years of age compared to subjects averaging 27.7 years old. In a recent study Luebberding *et al.* reported TEWL data from six different body sites on 150 women divided equally into five age groups, 18–29, 30–39, 40–49, 50–59, and 60–80 (107). No correlation was found between TEWL and age on the neck, forearm, or back of the hand. TEWL was negatively correlated to age on the forehead and cheek. Interestingly, TEWL on the décolleté area was positively correlated to age, ranging from 5.62 gm/m^2-hr on the youngest group to 7.86 gm/m^2-hr on the oldest, with a high level of statistical significance. In our review of the literature these data from the décolleté are the only ones to show a statistically significant increase in TEWL with age.

The SC barrier to penetration of compounds into the skin has also been evaluated as a function of age. Roskos *et al.* compared the penetration of six drugs of differing polarity into the skin of subjects 22–40 years of age and over 65 years old *in vivo* (108). Permeation rates for the two most hydrophobic drugs, testosterone and estradiol, were not significantly different between the two age groups but hydrocortisone, benzoic acid, acetylsalicylic acid, and caffeine all penetrated the skin of the older group at a significantly *lower* rate than into the younger. Rougier *et al.* also reported that benzoic acid penetrated older skin significantly more slowly than younger *in vivo* (79).

Analysis of all these results leads to the somewhat surprising conclusion that basal SC barrier function is relatively unaffected by age from childhood through late middle age and then may actually begin to increase slightly sometime after age 60. It is notable that this apparent improvement in baseline barrier function occurs in spite of the reduction in SC barrier lipids discussed above. Rogers *et al.* point out that while lipids decrease, the ratio of ceramides to other SC structural lipids remain approximately constant (95). It is also possible that skin permeation of some compounds through SC is slower because of the larger corneocytes. Rougier at al. found a negative correlation between corneocyte size and the skin permeation rate of benzoic acid *in vivo* (79).

Most studies indicate that the reactivity of skin to irritant may actually decrease with age, or at least is not more marked with age as one might expect. Bettley and Donoghue reported fewer reactions to patch testing with soap in subjects 50 and older compared to subjects 10–49 years of age (109). Grove *et al.* reported lower skin reactivity to a variety of irritants including dimethyl sulfoxide, ethyl nicotinate, and lactic acid (93, 110) in older subjects. Maibach and coworkers (106, 111) and Robinson (112) observed lower reactivity of older skin to sodium lauryl sulfate (SLS). Robinson also reported that reaction to

another strong irritant, octanoic acid, was significantly lower in subjects more than 55 years old while reactions to the weaker irritants acetic acid and decanol were only directionally reduced with age (112). Bowman *et al.* performed a ten-day cumulative irritation test comparing 26 subjects age 18–45 with 26 subjects age 65–80 using 11 products of widely varying irritancy (113). They found no statistically significant differences in response between the age groups, but the response was directionally less in the older age group for all the compounds that produced significant irritation.

While the static barrier function of the epidermis does not seem to diminish with age, recovery of barrier function after disruption has been found to be significantly slower in older skin. Ghadially *et al.* disrupted SC by either tape stripping or acetone treatment to the point that TEWL was increased to the range of 20–30 g/m^2-hr (105). Recovery of the barrier was quantified by measuring TEWL over the next several days. After acetone treatment young skin (under age 30) recovered its barrier function by 50% at 24 hours, while older skin (over 80) had only recovered 15% at 24 hours. Younger subjects took about four days to recover to 90% of their original SC barrier to TEWL while older skin required seven days to reach this level of recovery regardless of the type of insult (tape or acetone). The slower recovery of barrier function may be related to slower rates of epidermal renewal in older skin.

It is well known that corneocytes are continually shed into the environment and are being continually replaced by cells generated in the SG (see above). The SC "turnover time" is most frequently measured by staining the SC with the fluorescent dye, dansyl chloride, and monitoring the rate of dye disappearance with a UV light. When all of the fluorescence has disappeared, the SC has turned over completely (114). Grove and coworkers reported that SC turnover time is increased in elderly skin (76, 93). The turnover time for SC on the volar forearm increased from 19.8 ± 1.4 days in cohort under 35 years old to 28.1 ± 2.7 days in an over 60 age group. Similar changes were seen on the inner arm. These results confirmed the positive correlation between age and the time to turn over the SC reported by Roberts and Marks (115).

Grove found the number of SC cell layers was approximately constant between age groups, indicating that the increased SC turnover time results from decreased epidermal cell proliferation rates with age. Marks reported a small but statistically significant decline with age in the number of epidermal cells in the DNA synthesis phase (116). Engelke *et al.* investigated differences between young normal skin, young dry skin, aged normal skin, and aged dry skin (117)

using an antibody that stains the nuclei of proliferating cells (Ki-S3) (118). Antibody staining indicated a significant reduction in epidermal proliferation rate in aged “normal skin” compared to young normal skin. A slower rate of epidermal cell proliferation is consistent with the increased time to repair a disrupted SC barrier as reported by Ghadially (105). Grove also reported that small chemically induced blisters healed more slowly in subjects between 65 and 70 years of age than in subjects 18–25 years of age (119).

The greater tendency of older subjects to develop dry skin is well known (120–122). Elderly dry skin seems to be especially prone to itching (120, 123–126), which can sometimes be severe. Dry skin in the elderly tends to develop some distinctive patterns, especially on the legs. Figure 7 below shows dry skin that developed on the legs of three elderly subjects who lived in the desert Southwest. These pictures were taken after one week of washing twice daily with a standard soap and no use of moisturizers. Notice the distinct pattern of lines on some of the subjects.

Figure 7: Dry skin on the lower legs of elderly subjects (70–90 y.o.) after washing twice daily with a standard soap and avoidance of moisturizer use.

This pattern of lines frequently develops in elderly subjects but occurs rarely if at all in younger subjects (R.R. Wickett, personal observations). Treatment with an effective moisturizer reduces or eliminates the pattern in some subjects but not in others. In Figure 8 below we see that moisturizer treatment of the right legs has nearly eliminated the pattern in the subject on the left but had little effect on the subject on the right.

Figure 8: Dry skin resulting from soap use on the legs two elderly subjects. After one week of washing with soap and no moisturizer use the right leg of each subject was treated with an effective moisturizing lotion for two weeks while soap treatment continued on both legs.

It is not entirely clear why the elderly are so much more prone to developing dry skin. One possibility is reduction of levels of NMF (see above) in elderly skin. It has been shown that NMF levels are lower in dry skin (62). Data on the effect of age on NMF levels do not present a consistent picture. One of the key moisturizing components of NMF is the very hydrophilic molecule pyrollidone carboxylic acid (PCA) (56, 57) (see above). Harding *et al.* reported lower levels of PCA in elderly subjects and the difference was more marked deeper in the *stratum corneum* (70). Horii *et al.* reported a general decrease in free amino acids with increasing levels of dry skin in elderly subjects (127).

On the other hand, Jacobson *et al.* found that some SC amino acids decreased with age while others increased, but no difference was seen in total NMF free amino acids (FAA) normalized to protein content between young and old subjects (128). Takahashi and Tezuka (129) reported that NMF FAA actually increased in older subjects. However, both of these groups sampled the *stratum corneum* by scraping skin flakes from the surface rather than tape stripping to sample from lower levels of the SC as Harding *et al.* did. Further, as Tagami (96) has pointed out, Takahashi and Tezuka reported their results as FAA/corneocyte. Thus the higher levels of NMF FAA they report could be due to the presence of larger corneocytes in older skin (77, 78, 93) as discussed above.

Lactate is a component of the NMF that may be derived either from sweat (130, 131) or through anaerobic metabolism in the upper epidermis (132). Nakagawa *et al.* investigated the correlation between NMF components and SC stiffness, pH and hydration in summer and winter with healthy subjects (67). The only components that correlated significantly to SC stiffness and hydration were lactate and potassium. One might expect that the slower metabolism of aging skin reflected by the lower SC turnover rate might lead to lower levels of lactate in the SC. However, Prahl and coworkers reported that keratinocytes from aging skin produce higher levels of lactate *ex vivo* (133). It is well established that sweating rates decrease with age (134), which might lead to lower levels of lactate and thus stiffer, less well-hydrated SC.

Another factor in skin aging may be the reduction of sebum production that

occurs with age (135). Fluhr *et al.* have presented data from studies of asebic mice, indicating that glycerol derived from the hydrolysis of sebum contributes to skin hydration (136). Sebum production declines dramatically in women at menopause but does not really decline much in men before age 80 (135), so this seems unlikely to be the whole story either. It seems likely that the tendency for elderly subjects to develop dry skin has multiple contributing factors including lower PCA levels, the slower rate of SC renewal, lower levels of lactic acid due to reduced sweating, possibly reduced glycerol due to reduced sebum production, and other factors that have yet to be discovered.

There are been relatively few studies specifically comparing the effects of intrinsic and extrinsic aging on the SC. Tagami's group studied the dorsum of the hands of Japanese golfers who only wore a golfing glove on one hand (96, 137). Roughness of the skin surface was measured from silicon replicas. Interestingly, there was a significant negative correlation between the difference in roughness between exposed and covered hands and a golfer's handicap. Better golfers (lower handicap) had larger increases in roughness on their exposed hand. Hydration as measured by higher-frequency conductance was lower for the exposed site indicating a drier skin surface, but there was no difference in barrier function as measured by TEWL.

3.2.4.3 AGING AND THE DERMIS

Both intrinsic aging and photoaging affect the dermis far more dramatically than the epidermis. The papillary dermis is strongly affected by both intrinsic aging and chronic sun exposure. Figure 9 shows the effect of aging on abdominal skin of 18-and 76-year-old females. At the time these micrographs were published (1955) the abdominal skin of women received very little sun exposure, so the changes represent the effect of intrinsic aging.

Figure 9: Abdominal skin from an 18-year-old female (left) and a 76-year-old female (right). Note the flattening of the dermal-epidermal junction as the papillary dermis diminishes with age.- (modified from Andrew [138] with

permission of the Society of Cosmetic Chemists).

This flattening of the papillary dermis makes the skin less resistant to shearing stress, and the skin of elderly people is more easily ulcerated than that of younger people.

The thickness of the skin varies with age and changes depend on body site. In general, skin thickness increases for the first two decades of life. After this initial period, skin thickness may be fairly constant until about age 60. De Rigal *et al.* reported ultrasound results showing that skin thickness on both the ventral and dorsal forearm decreased significantly with age, but only after age 60 (139). Gniadecka and Jemec, however, reported a gradual decline in skin thickness on the forearms and ankles starting at about age 20 (140). Skin on the forehead and buttocks was found to increase in thickness with age. Takema *et al.* also found skin thickness to decrease with age on the forearms and increase on the forehead, corners of the eyes, and the cheeks (141). They interpreted this increased thickness as the result of sun exposure on the face.

3.2.4.4 THE DERMATOGLYPHIC PATTERN OF THE SKIN

Young skin shows a complex pattern of shallow lines on the surface. This dermatoglyphic pattern is altered on aging and a pattern with fewer but deeper lines that become more oriented emerges (93). Natural lines of tension in the skin called Langer's lines may influence the directional orientation. Hassan Zahouani and coworkers have studied these line patterns in detail (142–144). Figure 10 shows typical patterns from subject in various age ranges, pseudo-colored to indicate topography.

Figure 10: Changes with age in the dermatoglyphic pattern of human skin.

Figure courtesy of Hassan Zahouani, used with permission.

A highly aligned dermatogyphic pattern can also be seen on the legs of some of the subjects in Figure 8 above.

In addition to the flattened dermal-epidermal junction (Figure 9) and changes in the dermatoglyphic pattern, intrinsically aged skin has diminished collagen synthesis leading to reduced levels of collagen in the dermis (145–147). El-Domyati *et al.* reported that there is gradual loss of the transverse elaunin fiber network and shortening and eventual reduction of the oxytalin fibers, which were nearly gone by the ninth decade of life in sun-protected skin. Underlying elastic fibers in the mid to deep reticular dermis of sun-protected skin remained relatively unchanged in amount with age (146). Focal loss of elastin and clumping of elastin fiber bundles has been observed in sun-protected elderly skin in some individuals (148).

3.2.4.5 AGING AND MECHANICAL PROPERTIES OF SKIN

Skin is a viscoelastic material. Measurement of mechanical properties of skin *in vivo* is complicated by its complex, layered nature (Part 1). It is difficult to deform the SC without producing significant deformations in the underlying layers, and of course it is impossible to deform the dermis without deforming the SC. The general principle is that smaller deformations (minimum strain) will help to localize the response to the SC, and larger deformation will reflect more on the properties of the underlying layers (149).

The most commonly used instrument for measuring skin elasticity is the Cutometer® (150–152). The Cutometer uses negative pressure to pull the skin vertically into the opening of the probe (151, 152). Negative pressures can be controlled between 20 and 500 mbar. The height the skin raises into the probe is determined by an optical system. Probes with diameters of 2, 4, 6, and 8 mm are available. In the most widely used mode, deformation is measured while vacuum is applied quickly, held constant for a defined period of time, and then released (Figure 11).

Figure 11: Schematic of Response of Skin to Cutometer

Table 1 defines parameters that can be obtained from the Cutometer curve.

TABLE 1 Cutometer Parameters from Figure 11

Ue Elastic deformation of the skin due to the application of stress (vacuum)
Uv Viscoelastic creep occurring after the elastic deformation
Uf Total extensibility of the skin during stress application
Ur Elastic recovery due to stress removal
Ua Total recovery at the end of the stress-off period
R Amount of deformation not recovered by the end of the stress-off period
Ua/Uf Overall elasticity of the skin, including creep and creep recovery
Ur/Ue Pure elasticity ignoring viscoelastic creep
Uv/Ue Ratio of viscoelastic to elastic extension, called the viscoelastic ratio
Ur/Uf Ratio of elastic recovery to total deformation

Cua, *et al.* (153) used the Cutometer® to evaluate age and body site differences in the viscoelastic properties of skin in a study with 33 subjects, 17 of them elderly averaging about 75 years, and 16 young subjects averaging about 28 years. Measurements were performed on 11 body sites. Generally, Uv/Ue increased while Ur/Uf decreased with age, but differences were not significant for all body sites.

Smalls *et al.* (154, 155) investigated the effects of age, body site and skin thickness on mechanical properties of skin with the Cutometer® using the 6-mm probe in a 30-subject study. Uf on the shoulder measured by the Cutometer® was negatively correlated to age with $r = -0.78$ and $p<0.001$. Results are shown in Figure 12.

Figure 12: Uf on the shoulder versus age. Slope = –0.78, Reprinted from (155) with permission.

Ur and Ur/Uf also showed significant negative correlations with age.

Krueger *et al.* (156) investigated the effect of age and body site on Cutometer parameters with a panel of 120 women divided evenly into four age groups as follows.

Group	Age Range
I	20–29
II	30–39
III	40–49
IV	50–65

All of the viscoelastic parameters in Table 1 were measured. The mean correlation of Uf with age was –0.56. The parameter that had the strongest correlation with age was Ur/Uf, the ratio of immediate recovery to total deformation (R^2 = 0.656). Figure 13 shows their Ur/Uf results for each age group and body site.

Figure 13: Ur/Uf as a function of age for five body sites. Data taken from

Krueger *et al.* (156).

Ryu *et al.* (157) also reported a strong negative correlation between Ur/Uf and age in a study of 96 Korean women ranging in age from 20 to 75 years.

The reduction in extensibility and even larger reduction in elastic recovery with age is consistent with studies showing changes in the elastic fiber network of skin with aging and photoaging (146, 158–161). Ezure *et al.* (162) reported that Ur/Uf decreased as "sagging" scores increased on the cheeks of Japanese women. Warrier *et al.* found significantly lower elastic recovery (Ur) on the cheeks of Caucasian women compared to age-matched African American women (163) and attributed the difference to less photodamage on the face of African American women because of sun protection by melanin. Other studies have also shown that Ur/Uf is negatively correlated with age (141, 164). Increases in Ur/Uf by product treatment could possibly be used to substantiate anti-aging effects on skin elasticity.

On the other hand, dynamic indentation experiments performed by Boyer *et al.* indicate that the skin becomes more extensible with age (165). The authors attribute this difference to the fact that the indentation experiments were made without a "guard ring." The Cutometer deforms a small, well-defined area, determining the rheological properties of the skin, while dynamic indentation experiments deform a wider area and are proposed to be more reflective of the natural tension in the skin. Further discussion on the measurement and evaluation of skin elasticity and its relation to wrinkles and skin topology are extensively discussed in this book in the section on skin testing.

3.2.4.6 TELANGIECTASIA

Telangiectasia is the presence of visible blood vessels on the surface of the skin. It can occur both in sun-exposed and -protected areas of the skin with age. On sun-protected areas telangiectasia may develop because of thinning of the dermis.

Figure 14: Visible blood vessels (telangiectasia) on the outer thigh of a 64-year-

old male (nonsmoker).

Chronic sun exposure may lead to the development of telangiectasia (166, 167). Yano and coworkers have shown that acute sun exposure induces blood-vessel growth both by upregulation of vascular endothelial growth factor (VEGF) and downregulation of an important endogenous inhibitor of blood-vessel growth, thrombospondin (TSP-1) (168, 169). Upregulation of VEGF and downregulation of TSP-1 was seen in epidermal keratinocytes, endothelial cells, and dermal fibroblasts after UV-B exposure equivalent to two times the minimal erythema dose. Not surprisingly, new blood-vessel growth was also observed (169). The correlation between sun exposure and telangiectasia seems to be stronger in men than in women (21). Current smoking has also been reported to be strongly associated with the presence of telangiectasia (170).

3.2.4.7 PHOTOAGING MECHANISMS

The major factor in extrinsic aging of the skin is chronic sun exposure. It is well known that the majority of negative changes in skin's appearance, especially on the face, are primarily due to photoaging (171). Ultraviolet radiation affects skin cells through two mechanisms. The first is direct damage to DNA by UV-induced formation of DNA lesions, primarily pyrimidine dimers (7, 12, 172–174). DNA may also be damaged by reactive oxygen species (ROS) generated under the influence of UV exposure (175, 176). The ability to repair DNA damage through the Nucleotide Excision Repair system has been reported to decline with age (177), perhaps contributing to further compromise of sun-exposed elderly skin. Telomeres are especially sensitive to UV damage (178) and telomere shortening may significantly affect photoaging (172, 179, 180).

The second major factor in extrinsic aging is damage mediated by ROS, which in addition to damaging DNA, can cause skin changes either by direct action on cell surface receptors or by inducing the generation of cytokines (12, 173, 181–183). Figure 15 illustrates the effect of ROS-induced cytokine release on keratinocytes and fibroblasts.

Figure 15: UV radiation affects keratinocytes and fibroblasts through similar mechanisms. Reactive Oxygen Species (ROS) generated by UV exposure lead to cytokine production that stimulates the Mitogen-Activated Protein kinase pathway. MAP kinases are generated that cause the production of the transcription factor AP-1 and promotion of the synthesis of Matrix Metalo Proteinases (MMP) that break down collagen in the dermal matrix.

In both cases the Mitogen-Activated Protein kinase pathway is activated (181). This pathway involves a complex cascade of protein kinases (enzymes that catalyze the phosphorylation of other enzymes) that leads to the formation of the transcription factor AP-1 (184, 185). AP-1 has two important effects that contribute to photoaging. It promotes the transcription of messenger RNA for the production of collagenase and other matrix metalloproteinases that break down the dermal matrix, and it reduces the sensitivity of fibroblasts to transforming growth factor beta (TGF-β), reducing collagen production (173).

The hallmarks of photoaging in histology are seen in Figure 16. Both type I and type III collagen are reduced (146, 186, 187) except in the thin band right below the epidermis called the Grenz zone. The SC and epidermis may be slightly thickened, though not all authors agree on this point. The major characteristic difference between photoaging and intrinsic aging is the presence of elastosis (146–148, 188). There is actually a large accumulation of elastic fibers in the dermis of severely photoaged skin, but these fibers are dystrophic, with large accumulations of condensates including lysozyme and amyloid P protein (189), which protect the deranged elastin from digestion by elastase (190). The fibers that result from actinic elastosis provide little or no elasticity to the skin.

Figure 16: Hallmarks of photodamage as seen in histology. From Robert Lavker, MD. Skin aging and photoaging: Presented to Congress of the International Society for Bioengineering and the Skin, Orlando, FL. October 28, 2004, reprinted with permission.

As solar damage progresses, inflammatory cells migrate into the dermis. The vasculature changes that may result in telangiectasia have been discussed above.

3.2.4.8 PHOTOAGING AND APPEARANCE

The visual signs of photodamage are well known and include wrinkles around the eyes and mouth, hyperpigmentation (age spots), telangiectasia, and deep furrows in the skin in exposed body sites (158, 191–193). Figure 17 shows classic signs of photoaging on some well-known faces.

Figure 17: Classic signs of photoaging (public domain publicity stills taken from www.skinema.com)

Both subjects have extensive wrinkling in the around the eyes in the peri-orbital or so-called crow's-foot area and around the mouth. The subject on the right spent much time filming in the sun while wearing a cowboy hat. Notice that the skin on the forehead looks better than the skin lower on the face.

Corcuff *et al.* analyzed wrinkling in the peri-orbital area on 81 subjects ranging in age from six to 76 years (194) using image analysis of silicone replicas. Results are reprinted in Figure 18.

Figure 18: Evolution of "crow's-foot" wrinkles with age. Number of wrinkles per cm^2 ± S.E. b. means depth of wrinkles (µm ± S.E.). Reprinted from (194) with permission of the Society of Cosmetic Chemists.

Interestingly, the number of wrinkles peaked at about age 35, but mean wrinkle depth increased by eightfold between age 35 and 65.

Sun-induced changes can occur at an early age if sun exposure is sufficiently extreme. Corcuff, de Rigal, and Leveque did a very interesting study on riders in the 1985 Tour de France (195). Professional cyclists spend many hours in the sun and wear tight-fitting short-sleeved shirts while training, providing a sharp divide between exposed and sun-protected areas of skin. Even though the average age of the riders was 25 years, there were dramatic differences between protected and exposed skin. The line pattern on the exposed skin sites of these young cyclists resembled that seen in the >71-year age group in Figure 10. The average furrow depth in the exposed sites was 42 ± 1.5 mm on the exposed sites compared to 29.5 ± 1.0 mm on protected sites.

3.2.4.9 COMPROMISED ELDERLY SKIN TREATMENTS

a. Sunscreens—an ounce of prevention

Since sun exposure plays such an important role in compromising skin, it seems obvious that sunscreen use is a good strategy to prevent damage. However, this is difficult to prove in humans. Long-term studies are required, and it is not ethical to give people a "placebo" sunscreen.

The most convincing study on sunscreen use and photoaging that has been published to date was done as part of the Nambour Skin Cancer Prevention Trial, a randomized, community-based trial in Nambour, Australia (196, 197). In this study, conducted from 1992 to 1996, some subjects were required to apply an SPF 15+ sunscreen daily while others only used sunscreens at their discretion. The photoaging trial was conducted on a subset comprised of 903 subjects who were under 55 years of age to emphasize the effect of photoaging compared to intrinsic aging (198). Dietary supplementation with β-carotene was also

investigated. Photoaging was measured by using a validated method based on grading silicone replicas from the backs of the hands on a scale ranging from 1 (no damage) to 6 (deep horizontal lines and loss of vertical lines) (199, 200). Reported sun exposure was similar between the daily and discretionary sunscreen groups. Participants with initial grades of three or four showed reduced skin aging in the daily sunscreen group compared to discretionary use and significantly reduced skin aging after 4.5 years in the study, compared to those who only used sunscreens at their discretion. Results with the group given oral supplementation with β-carotene were not different from placebo.

The study described above showed that regular sunscreen use can have a significant effect on the rate of photoaging. When we consider that modern sunscreens tend to be higher SPF and broader spectrum compared to those used in the early 1990s, it seems logical that they could provide an even better protective effect, but the data indicate that very regular use is likely to be required, rather than just casual application when one goes out for prolonged exposure.

b. All-Trans Retinoic Acid (Tretinoin): The Gold Standard

Tretinoin is the only drug approved by the United States Food and Drug Administration for the treatment of wrinkles. It was first reported to have positive effects on photoaged skin by Albert Kligman and colleagues (201) in 1986. During the 1990s, tretinoin was investigated in double-blind, vehicle-controlled clinical studies (202–204). Olsen *et al.* performed a 320-subject multicenter study comparing 0.05%, 0.01%, and 0.001% tretinoin to vehicle on the face (205). After 24 weeks of treatment, 0.05% tretinoin produced statistically significant improvements in grades for overall severity of photodamage, mottled hyperpigmentation, fine wrinkling, and skin roughness compared to vehicle. Other studies showed that tretinoin was very effective for treating “liver spots” associated with photodamage (206) and hyperpigmented spots in Asian subjects (207). Grove and coworkers used image analysis of silicone replicas to demonstrate that 0.05% tretinoin consistently improved skin topography more than vehicle (208).

c. Cosmeceutical Treatments for Aging Skin

Tretinoin is a pharmaceutical product and an approved drug. Cosmetic treatments designed to improve aged skin are often referred to as “Cosmeceuticals.” While Albert Kligman, MD, is often said to have coined this term in the 1980s, it actually predates that time. The first published use of the

term we are aware of is by Raymond Reed, published in the *Journal of the Society of Cosmetic Chemists* in January 1962 (209). However, Reed's definition is so broad as to include simple moisturizers and other ingredients that probably wouldn't be considered "cosmeceuticals" today. Certainly Kligman popularized the term and played a significant role in the development of its current usage to refer to cosmetic ingredients that have activities that provide skin effects such as anti-aging (210). It is also important to keep in mind what the FDA says about "cosmeceuticals (211)"

The FD&C Act does not recognize any such category as "cosmeceuticals." A product can be a drug, a cosmetic, or a combination of both, but the term "cosmeceutical" has no meaning under the law.

Perhaps this is why, even today, the exact definition of cosmeceutical is not totally clear (212, 213). A significant literature exists on cosmeceuticals, even though the FDA says the term has no legal meaning and there are many reviews on the subject (212, 214–227). We will now briefly review a few of the many "cosmeceutical" actives.

d. Vitamin A and "Cosmeceutical" Derivatives

Retinol and retinol esters are popular ingredients in skin care products designed to treat the signs of skin aging. Retinol produces some changes in skin that are similar to tretinoin (228). It is much less effective but also less irritating (228, 229). Pierard-Franchimont *et al.* showed that retinol treatment can produce improvements in the mechanical properties and topography of skin (230). Retinol still has the potential for skin irritation and can be unstable. This has led to investigation of retinol derivatives such as acetate, proprionate, and palmitate esters (216, 231). These esters are presumably metabolized to retinol and the free acid in the skin as has been demonstrated with retinyl palmitate (232). Bissett presented data showing that 0.15% retinol and 0.3% retinyl propionate can have positive effects on both wrinkling and hyperpigmentation after 12 weeks of treatment (216). Retinol has also been reported to improve intrinsically aged skin (233).

e. Niacinamide

Niacinamide, also known as nicotinamide, is the amide of nicotinic acid (vitamin B_3). In the cell it is incorporated in nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate, which are vital to energy metabolism. Topical application of niacinamide has been shown to have many positive effects on the skin, including improving barrier function (234–237),

reducing the appearance of fine lines and wrinkles (234, 238), and improving hyperpigmentation (239, 240). The improvement in skin pigmentation is apparently through a reversible effect on the transfer of melanosomes from melanocytes to keratinocytes (240, 241).

f. Alpha and Beta Hydroxy Acids

As pointed out above, the turnover rate of the SC decreases with age. Lactic acid had been well known as a moisturizer for many years (242–244), but the observation that lactic and glycolic acid increase the rate of SC turnover (245, 246) led to great interest in their application as potential anti-aging treatments. Stiller *et al.* published a double-blind placebo-controlled study comparing 8% lactic and 8% glycol acids to vehicle on signs of photoaging on both the face and forearm (247). Both lactic acid and glycol acid were significantly better than vehicle in improving global photoaging scores, and the two hydroxy acids were not different from each other. The so-called beta hydroxy acid products are based on salicylic acid, usually at about 2% concentration. This topic is described in great depth elsewhere in this book under the Ingredient section.

g. Antioxidants

Since reactive oxygen species play such an important role in photoaging, it is not surprising that antioxidants have been a major focus of cosmetic research. Vitamins E and C are probably the most studied for their potential to protect the skin from photoaging and treat its symptoms (216, 248–259). Raschke reported that 3% ascorbate had a significant effect on reduction of facial wrinkles compared to vehicle, but only when delivered from an “optimized formulation” (256). Antioxidants from plant sources are also under study. Green tea polyphenols have been the most studied ingredients in this regard. While studies in murine skin have shown promise (260, 261), human skin clinical trials of both topical (262) and oral (263) green tea treatment have failed to show visible benefits on skin aging. Histological evaluation after topical treatment for eight weeks did show significantly improved elastic tissue compared to placebo (262).

h. Other actives

A wide variety of other ingredients that can potentially improve the condition of compromised elderly skin are under investigation or have been investigated. They include peptides (221, 264, 265), topical application of estrogen cream (266) (a pharmaceutical not a cosmeceutical), anti-glycation compounds (267), and a variety of botanical ingredients (268).

CONCLUSIONS

As we age, our skin undergoes obvious changes. Some changes occur even on body sites not exposed to the sun or other insults. This intrinsic aging results from the unavoidable effects of the passage of time. Some of our daily activities not only accelerate the aging of skin but also alter its consequences, thereby leading to extrinsic aging. The most important contributor to extrinsic aging is exposure to the sun, though exposure to cigarette smoke may also contribute. Sun-exposed skin ages more rapidly than unexposed skin and differences in histology appear. For example, in chronically sun-exposed skin collagen decreases but elastin increases, though it is often highly dystrophic, while in intrinsic aging both collagen and elastin decrease.

This chapter has reviewed the effects of both intrinsic and extrinsic aging on the skin. Perhaps because of its vital function, the *stratum corneum* barrier is relatively unaffected by age, though barrier repair and wound healing may be slowed. The tendency of the Aged to develop dry skin is clear, and this may contribute to the appearance of fine lines and wrinkles. Changes in the dermis result in changes in the dermatoglyphic pattern of the skin and deeper wrinkles. Chronic sun exposure has profound effects on skin, leading to solar elastosis and the development of deep wrinkles and “age spots.”

We have also reviewed prevention and treatment of skin damage. Skin damage from the sun may be reduced or even prevented by frequent use of sunscreens. Tretinoin is the only FDA-approved drug for the treatment of wrinkles. Studies over the past three decades have shown the effect of tretinoin on photodamage, hyperpigmentation, wrinkles, and skin roughness.

Many cosmetic ingredients and products are alleged to provide effective treatment for the appearance of aged skin. The literature on some of the most common of these treatments was reviewed. Retinol derivatives, antioxidants, and niacinamide are among the treatments reviewed. While there is ample evidence that some “cosmeceutical” treatments may be effective for treatment of the signs and symptoms of skin aging, manufacturers must be careful that claims about product efficacy are restricted to those appropriate for cosmetics based on existing regulatory statutes in the U.S. and elsewhere.

THE HAIR

Editors Overview

Dr. Manuel Gamez-Garcia, Ph.D.,
Research Fellow,
Ashland Specialty Ingredients

Over the last ten years our understanding of hair and its care has developed significantly with the application of new scientific approaches and the resulting breakthroughs that have emerged.

In the area of cosmetic science, a large number of the aesthetic properties of hair have unequivocally been linked to the physical and viscoelastic properties of either the cuticle or the cortex. Various layers of the cuticle sheath have been shown to play an important role in hair lubricity, damage protection, and optical properties. The crystalline and amorphous phases contained in the ortho-and para-cortical cells of the hair shaft have been shown to be crucial for most hair-shape aesthetic modifications induced by consumers and cosmetologists' use of harsh cosmetic treatments such as the application of heat, exposure to alkaline formulations such as those used in hair relaxation, and other chemical-reducing aqueous solutions. Denaturation of crystalline regions, disulfide bond scission, and breakage of other protein bonds are all phenomena that have been carefully analyzed to assess their impact on the aesthetic aspects of hair and its damage.

In the area of hair biology, various important contributions have also been made. For instance, the role of stem cells, hormones, and other cytokines on hair growth; the discovery of additional stages in

the hair growth cycle; the biochemical basis for hair graying and aging, and the impact of new bioactives and other nutritional supplements in the health of hair are all relatively new discoveries just made within the last ten years.

With these rapid advances in the various hair-related areas, the science of hair care is unavoidably moving towards a more holistic approach. Such an approach considers the aesthetic properties of hair not only as a by-product of cosmetic treatments to the mature and keratinized form of the hair shaft, but also as a result of the action of bioactives that can enhance or improve the overall condition of hair while its cells are still alive in the hair follicle. This trend is quite significant when one considers that we used to think of hair as “dead,” and now our thinking and knowledge have evolved to focusing on the distinction that the cells in the mature hair shaft may be s “dead” but its proteins are still biologically active. Furthermore, by penetrating to the roots of the hair shaft, we have “discovered” that it is still *alive* while in the follicles, and this realization has created a paradigm shift in thinking of new approaches to bring beauty to what both men and women treasure as a major part of looking and feeling young.

It is within this context that the material in this section was chosen and organized. It starts with an overview of hair structure and function, followed by an overview of hair follicle biology. It then continues with a chapter on aging hair, hair loss, hair dyes, and bioactives, followed by a discussion on the mechanisms of changes in hair shape. The last chapter deals with eyelashes, including their anatomy and methods for increasing their growth.

The five chapters in this part of the book introduce fundamentals of hair science that range from its structure, mechanistic changes in shape and growth, to the action of bioactives to improve its health. This material provides a solid base in what we would now term “Hair Science” for beginners and fresh insights for seasoned researchers. The various contributors to this hair section were encouraged by the

book’s editor-in-chief to not only give an in-depth overview of their various topics but also to present new insights and new ideas emerging in the area of hair care.

AN OVERVIEW OF THE PHYSICAL AND CHEMICAL PROPERTIES OF HAIR AND THEIR RELATION TO COSMETIC NEEDS, PERFORMANCE AND PROPERTIES

Author

Ashland Specialty Ingredients

ABSTRACT

In this chapter we present an unusual approach to the subject wherein we consider the system of hair structure and its relation to hair function. The approach used for this purpose consists in reviewing the most recent and advanced hair structural concepts derived from the fields of chemistry and biology, while providing a strong emphasis on the physical, social, and cosmetic aspects of hair function.

The chapter is divided into six parts:

- The four first sections describe the chemical and biological composition of hair, which forms the foundation for its complex physical architecture. Through these sections a detailed analysis is made of the hair internal structure, its viscoelastic and optical properties, and its response to moisture. Wherever possible an effort is made to always connect physical properties and related processes with the functional aspects of hair.
- In the last two sections, a review is made of the various processes taking place in the follicle to create hair. We point out that the follicle is *alive*, and that the native proteins in mature hair still have biological activity and a

function to play. This provides access to cosmetic approaches to improve its beauty, and of course, it is a relatively new concept since the hair protein architecture has long been considered as a structure with no biological activity. There a description is made of the main biological activities occurring in the various zones and phases of the follicle to assemble cells and produce hair. As this description is made, special attention is given to the follicular activities that create, from its inception, the foundations that correlate hair architectural structure with hair function. We assert that this unique approach and a true understanding of the relationship between hair architecture and functional biology opens an entirely new field for the development of new concepts and products for the cosmetic and personal care industry catering to both men and women.

TABLE OF CONTENTS

3.3.1.1 Introduction

3.3.1.2 Chemical composition of hair

3.3.1.3 Main types of hair cells

3.3.1.4 Cortical cells and their role in hair properties

3.3.1.1 INTRODUCTION

It is a general principle of nature that any living organism, or biological material created by nature, is made and structured in such a way that its properties are optimized to perform a specific function. In this sense, hair is not different from any other biomaterial found in the organs of our body. Contrary to the common belief that hair is a dead material and of little or no importance, hair is an optimized assembly of proteins, lipids, and polysaccharides organized into units or cells for a specific function. All cells in our body undergo a life cycle and are created to fulfill a function. However, in this respect there is a considerable difference between hair cells and other organ cells. Cells from other parts of the body undergo a programmed form of cell death, known also as “apoptosis,” once they have fulfilled their function. After this event, the cells are discarded and eliminated from the body. In contrast, when hair cells die by “apoptosis” in the follicle, their function is not finished; rather, it has just begun. Thus, when hair cells die, they are not discarded by the body because it is then that they are needed the most for their specialized biological function of scalp/skin protection and aesthetic purposes. The short-lived period of hair cells in the follicle is just a preparatory stage for their final function.

Another common belief is that since hair cells are inanimate or lifeless, their structure has no biological activity. This statement is somewhat incorrect because the protein structure of inanimate hair cells still possesses biological activity that is crucial for our living organism. Even when hair cells are dead and inanimate, if their protein structure is damaged, as in the case of enzyme structures, their biological function is compromised. Let us remember that enzymes are lifeless protein structures whose activity plays a critical role in many of our biological processes. Enzymes are not living organisms, and they lose their biological activity when their natural conformations are lost by denaturation due to harsh stresses, either thermal, chemical, or mechanical (1).

Likewise, the proteins composing our hair cells also lose their biological function/activity when they are subjected to harsh stresses, i.e., heat, chemical

treatments, mechanical fatigue, or excessive mechanical elongations. Hair treatments with hot irons and with other chemical processes such as perm waving, bleaching, and alkali straightening are known to cause denaturation and bond breakage in hair's native proteins (2). As a consequence, many hair properties are compromised, i.e., hair loses the ability to control moisture absorption. Its mechanical/thermal/optical response is compromised, and ultimately it loses its aesthetic purpose and ability to protect the scalp. Thus, the chemical composition and protein architecture of inanimate hair cells still possess biological activity enabling hair to fulfill the biological function for which it was created.

3.3.1.2 STRUCTURE AND CHEMICAL COMPOSITION OF HAIR

Hair is composed of proteins and a very small quantity of lipids and polysaccharides. These biomaterials form the hair cells, which are spatially separated and sequentially organized in a brick-and-mortar fashion in the cylindrical hair body. Consequently, they form membranes, amorphous and crystalline protein regions that extend all along the hair fiber, giving rise to the complex architecture of hair (see Figure 1). As will be seen later, these structures are the foundation of hair's remarkable physical properties. Table 1 displays the overall amino acid chemical composition of hair (3); the data in this table clearly show that hair is rich in half-cystine, serine, glutamic acid, and proline, i.e., the amino acids characteristic of a protein known as keratin. The next most abundant materials in hair, although at a smaller scale compared to the amount of protein, are lipids and polysaccharides, which account for 2–10% of the fiber weight. These materials, as will be discussed later, mainly appear in the cement layer gluing cortical and cuticle cells, as well as on the hair surface.

Another substance that is always present in hair is water. Incidentally, water is never considered part of the hair composition. Surprisingly, many scientists consider water to be an integral part of most biologically active proteins and, therefore, for all practical purposes water is also part of the hair composition. Native proteins contain a substantial amount of water in two forms, namely bound and free water. Free water, also referred to as "bulk water" or "loose water," has only a minor influence in the native structure of proteins. In contrast, "bound water," with its strong binding physical forces, attaches to specific protein groups stabilizing the protein secondary structure (4). Bound water plays

an important role in the conformation of exposed side chains, and because of its role on protein stabilization many scientists consider it to be part of the protein structure. Water is thus also part of the hair keratin composition (5) because it is needed for its stability. The role of water on hair behavior will be discussed in further detail later in this chapter.

Percentages amino acids in hair:

Alanine	4.6
Arginine	5.8
Aspartic acid	4.9
Half-cystine	17.8
Glutamic acid	11.4
Glycine	6.4
Histidine	0.9
Isoleucine	2.6

3.3.1.3 MAIN TYPES OF CELLS IN HAIR

A hair fiber is mainly composed of three types of cells, namely, cortical, cuticle, and medulla cells (see Figure 2). These three types of cells are made, organized, and assembled to form hair fibers by a tiny organ called the follicle (see Figure 3). This small organ sits on the scalp, and there are as many follicles as hair fibers. While hair cells are still alive in the follicle, they acquire a protein structure, composition, and architecture that prepare them for their final function. Before the hair cells undergo apoptosis the follicle carefully feeds and instructs them so they can arrange their internal protein structures into highly specialized conformations. For instance, a large percentage of the proteins found in the cortical cells of hair are arranged into a type of peptide sequence and conformation that is unique among all proteins. This unique protein is called keratin and its helical structure is such that, later, it allows hair to attain a high degree of mechanical strength (see Figure 4).

Keratin is a protein designed by nature to provide mechanical strength wherever needed in living organisms (6). Keratin proteins are usually coiled into filaments and constitute the micro-skeleton that gives mechanical stability to many cells. Without keratin filaments, many living cells would burst or collapse under the action of fluid pressure; i.e., in the liver they act as scaffolding structures that provide mechanical strength to the hepatocytes (7). Depending on their mechanical characteristics, keratins can be divided into alpha and beta keratins, or soft and hard keratins, respectively. Alpha or soft keratins are mostly found in hair, nails, skin, other body cells, wool, and the fur of other mammals, while the hard beta keratins are typical of reptile claws, the shell of turtles, *etc.* (8). Alpha keratins are also classified as type I (acidic) and type II (basic) keratins, and, in hair they are always coiled in pairs (9–10). Keratins can vary in structure and molecular weight, and therefore, there is a large variety of them; however, regardless of their type, nature always uses them when there is need for mechanical strength.

Figure 3: Diagrammatic representation of hair follicle with its main general components and the lipid gland (62).

Figure 4: Helical structure of alpha helix in keratin.

3.3.1.4 CORTICAL CELLS AND THEIR ROLE IN HAIR PROPERTIES

a. Cortical cell structure and composition

The cortical cells are elongated and spindle-like in shape; they constitute the major cellular component of hair fibers and are responsible for most of the mechanical properties of hair (10–11). Their irregular circular shape in a grown hair fiber has an average diameter of approximately 20 µm; their entire body length is approximately 100 µm long (see Figure 2). The cortical cells in grown hair fibers are not alive. However, before the hair fibers emerge from their follicles there is a point at which they are still alive. The main task of these cells during their life period is to synthesize keratin proteins in their bodies by assembling key amino acids into helical structures, strand them into filaments—also called intermediate filaments (IFs), and finally, bind them via disulfide bonds to an amorphous protein matrix to form macrofibrils (11–14). The amorphous protein matrix gluing the microfibrils will then be crosslinked with disulfide bonds and hardened as the cells die. The keratin filaments are crystalline in nature and are known to possess remarkable mechanical strength. To further maximize the mechanical resistance of the nascent hair fiber, the follicle facilitates the creation of hundreds of cortical cells and instructs them to interdigitate and produce an extracellular material, the cell membrane complex (CMC), which glues them all together in a cylindrical shape (Figure 5).

Figure 5: Schematic representation of cell membrane complex in hair fiber.

Because the cortical cells contain high levels of keratin, the resistance of a hair

fiber to mechanical breakage is comparable to that of a copper wire of the same diameter. Yet, in spite of this remarkable mechanical strength, the hair fibers do not behave like rigid metallic wires. We all know that hair fibers on the scalp are rather soft and easy to bend and move. This motion allows them to separate and create inter-fiber pockets of air needed for sweat transfer, thermal insulation, scalp protection, and aesthetic purposes (15, 16). Unlike a bundle of copper wires, hair is known for exchanging moisture with the environment by a physical process of absorption and desorption that involves heat transfer with the environment. This process, which occurs also in wool fibers, allows them not only to act as insulating materials, but also as heat buffers that effectively regulate skin/scalp temperature (17, 18). Furthermore, from a cosmetic point of view, hair fibers do not behave like copper fibers since an assembly of hair fibers can be deformed or styled into any desired shape with the aid of water, and it can later recover its original shape.

This particular behavior of hair, which combines mechanical strength with softness and moisture absorption/desorption with heat exchange, is at the base of its biological and cosmetic function. This combination of properties results from the biological activity of hair proteins with their unique architecture within both cortical and cuticle cells. The biggest contribution to this behavior comes, however, from hundreds of keratin microfibrils embedded in a protein-amorphous matrix in the cortical cells. The keratin microfibrils have a high degree of molecular order. Being crystalline, they do not swell in water, while the amorphous phase has no order, and a part of its structure is highly swellable by water. In terms of strength, the combination of keratin microfibrils embedded in an amorphous phase is akin to that of an epoxy composite material reinforced with glass fibers. In this sense a single hair fiber can be considered as an amorphous protein matrix reinforced with keratin microfibrils.

b. Viscoelasticity in hair and cortical cells

In 1959 a mechanical model was proposed by Max Feughelman (15, 20, 21) to explain the remarkable relationship existing between elasticity, softness, strength, and moisture displayed by wool and hair. This scientist considered that the outstanding mechanical behavior of hair and wool and, in general, of most keratin fibers, results mainly from the mechanical response of keratin microfibrils, or intermediate filaments (Ifs), embedded in an amorphous protein matrix forming macrofibrils in the cortical cells.

In order to explain the time-delayed elasticity associated with hair softness and

its dependence on moisture, Max Feughelman introduced the concept of viscoelasticity to keratin fibers. He proposed a two-phase mechanical model that didn't take into account the discrete nature of cortical cells, cell membrane complex (CMC), and cuticle cells. He thus generated a model of the hair fiber as if it were a continuum material—made only of keratin microfibrils embedded in an amorphous protein matrix (see Figure 6). In this model, now supported by a large amount of experimental evidence, the keratin microfibrils (C phase) are considered to act mechanically like rods in parallel with the amorphous phase (M phase M in which they are embedded) (15).

Figure 6: Representation of Max Feughelman mechanical model of keratin fibers showing keratin rods embedded in an amorphous matrix (20).

Since the introduction of the Max Feughelman model, three other models have been proposed to explain the mechanical behavior of keratin fibers. The main differences among all them seem to center on the way the amorphous phase interacts with the crystalline phase. A more detailed discussion of these differences can be found elsewhere (21). For the purpose of this chapter it suffices to emphasize, however, that all of these models recognize the existence of the amorphous and crystalline phases as two separate entities with different mechanical behavior. In all these models it is agreed that the amorphous protein phase corresponds to the zone of scrambled proteins surrounding the keratin microfibrils. The proteins in this zone constitute the "cement" that supports and interconnects, via disulfide bond crosslinking, hundreds of microfibrils to form the macrofibrils we know as "hair."

Within the amorphous matrix, the two-phase mechanical model recognizes the

existence of two regions with different cystine content, namely, the high-and low-sulfur regions. The low-sulfur amorphous region is considered to be in close proximity to the microfibrils, while the high-sulfur region is further away from them. Furthermore, the amorphous phase contains hydrophilic and hydrophobic protein groups that form extended structures all along the cortical cells. Because of these two structures, the amorphous phase can display two distinct patterns of physical behavior. The first one consists of a softening effect usually observed when the amorphous phase interacts with water. The softening effect is due to the hydrophilic extended structure of the amorphous phase and is also referred to as the “gel structure” by Max Fueghelman (20). This structure absorbs large amounts of water, is susceptible to plasticization by moisture, and its viscoelastic response is moisture dependent. In contrast, the non-gel structure of the amorphous phase is hydrophobic, highly crosslinked, and softens at very high temperatures.

Phase C comprises the crystalline keratin rods forming the macrofibrils. As a result of their crystalline character, these rods do not to absorb water, and therefore, cannot be plasticized by water. The macrofibrils thus act like strong micro-springs that respond only elastically to mechanical stresses. Thus, macrofibrils and amorphous phases combine their mechanical and water absorbing/desorbing properties to make hair a viscoelastic material. Because the content of crystalline keratin macrofibril protein in hair is approximately 95%, a hair fiber has a melting temperature (Tm) of ~ 156°C. Hair has also a glass transition temperature (Tg) of ~ 144°C, and it is primarily related to the noncrystalline amorphous matrix (23). Let us not forget that the Tg in polymers or biopolymers is nothing but the temperature at which a hard amorphous polymer becomes softer (24). Therefore polymers that are very hard and brittle at room temperatures can be softened, by raising their temperature to their respective Tg. They can also be softened by adding a plasticizer. In fact, hair fibers are biopolymers, which under dry and room-temperature conditions are mechanically hard but can become softer, either, by raising their temperature above 174°C, or by adding a plasticizer. We are all familiar with the fact that water is the natural plasticizer for proteins. Thus, hair without moisture is hard and brittle, but when it absorbs moisture it becomes softer because the gel structure of the amorphous phase becomes plasticized by water. This plasticization effect by water is clearly shown in Figure 7, where it can be seen that the amount of force needed to deform a hair fiber is always lower when it has higher levels of moisture.

Figure 7: Typical stress-strain deformation curves of hair fibers obtained at three different moisture conditions (60).

The effects of water plasticization/softening in hair are more significant when hair fibers are deformed below 2% water level. The reason for this is that the main hair component that responds to low deformations is the gel structure of the amorphous phase with its large number of hydrogen bonds. At deformations (d), 2% > d < 40% the mechanical response of the fiber is not influenced by the presence of water. Rather, it is mainly controlled by the unfolding of the alpha-keratin into the beta-keratin configuration. Unfolding of the alpha helical keratin in the microfibrils thus allows for larger deformations in the hair fiber, thereby preventing it from immediately breaking in the yield region. The transformation of keratin from the alpha to beta configuration is a thermodynamic phase transition and can be induced in hair by many processes other than mechanical extension. When it is produced by heat or chemical damage, it is usually irreversible; however, when it is induced mechanically it is fully reversible. The beta configuration of keratin sometimes is also called the “ladder or platelet” keratin structure (22, 23). Deformations larger than 5%, giving rise to keratin unfolding, occur in hair in daily grooming practices. They occur mostly upon repetitive combing, in particular, when the hair is wet or when the hair is still wet and is being detangled.

The stress/strain curve of hair is shown in Figure 8, where it can be seen that when we deform a single hair fiber from 0 to approximately 40% in length, the hair displays three different slope regions of force versus deformation. The first line is comprised between 0 and 2 or 5% deformation depending on the relative humidity of the environment (segment A). It is known as the Hookean region and has the steepest slope. This region represents the stress/strain mechanical response of the amorphous and crystalline (alpha keratin) phases. In particular, it

represents the mechanical response of protein region with hydrogen bonds. Since these levels of deformation are easily attained with everyday combing and grooming practices, we stress the amorphous and macrofibril phases of our hair almost everyday. If we continue to deform the hair fiber between 2 and 35% (segment B), the slope stress/strain changes because it is produced by a different phenomenon, namely, the opening of keratin coils in the macrofibrils. This section of the stress-strain curve of hair is known as the yield region. Hair deformations falling in this range are typical during excessive tangling when the hair is wet. Deformations higher than 35% cause the final change in slope before the fiber breaks; the physical phenomenon associated with these deformations seems to be a process of recrystallization of the amorphous phase (segment C) (11).

Figure 8: Stress strain curve for hair up to 30% deformation.

c. Shape-memory properties of hair

It is known from the field of polymer science that the mechanical behavior of polymers can be characterized as either being of the thermoset or thermoplastic type. Thermoset characteristics are those that do not respond to temperature changes, while thermoplastic characteristics refer to those materials that soften when heat is applied.

When polymers contain a high level of crosslinking bonds, they are usually of the thermoset type. In many cases these materials behave also as “smart” materials displaying shape-memory properties (24, 25). Since approximately 90% of the hair is composed of cortical cells filled with crystalline and amorphous proteins crosslinked by disulfide bonds, hair like any other polymeric crosslinked material behaves also as a thermoset, viscoelastic, shape-memory

biopolymer. Thus, hair has a permanent shape that may be temporarily changed, but can also be reversed later under the appropriate conditions. For instance, whether the hair is limp, wavy, curly, or extremely curly, it will always remember its native shape regardless of what type of styling shape has been imposed on it. Furthermore, the fact that the hair geometry can successfully be changed after styling, and held there for a certain period of time without the hair immediately recovering its shape, is by far one of the most important cosmetically useful examples of hair viscoelasticity and memory-shape properties. If the behavior of hair were purely elastic, hair would not be able to easily deform and accommodate for deformations needed for fiber separation, air pocket formation, thermal insulation, scalp protection, and aesthetic purposes. Also, hair would not be able to transiently change its shape during styling for cosmetic purposes. Thus, hair is a viscoelastic shape-memory material, *and failure to comprehend this will hamper our understanding of one of the most fundamental properties of hair's biological and cosmetic behavior*.

d. Viscoelasticity and the shape-memory properties of hair

Because of the great importance of viscoelasticity in the shape-memory properties of hair, a brief review of this concept will be helpful. We are all familiar with the fact that when a small force is applied to a pure elastic material, for instance, to a rubber band, it will deform a certain short distance. Then, when we release the force, the rubber band will recover almost instantaneously to its original shape. In this process it is obvious that the energy applied to deform the rubber band is stored as mechanical tension energy, and then returned when the force is released. In contrast, in a pure viscous material this does not happen. Rather, when we apply a similar force to a viscous material, for instance, to a string of chewing gum, a small deformation is also produced. However, contrary to the elastic material, the string of chewing gum will not recover its original shape once the force is released and it will stay deformed forever. Furthermore, the energy spent to deform a viscous material like the string of chewing gum is not returned but rather, it is dissipated as heat (26). In summary, an elastic material—when deformed—recovers its shape instantaneously when the force causing the deformation is released, while a viscous material does not.

A viscoelastic material, like hair, displays both behaviors simultaneously, namely, viscous and elastic. In fact, we all have daily encounters with materials that behave viscoelastically. For instance, when we apply a force for a short period of time, i.e., for one second, to a piece of plastic film from a sandwich

bag, it will deform slightly. The shape of the film will be recovered instantaneously again when we release the force. However, if we now apply the same force, but for a longer period of time, let's say five minutes, we will still produce the same deformation, but we will notice that when we release the force, the plastic film does not recover its original shape right away. If we wait for some time and pay careful attention to the plastic film, we will notice that it slowly crawls back and eventually recovers its original shape.

In the above example, with a one-second force application, the piece of film displayed typical elastic behavior; yet in the case of a five-minute force application the same plastic film showed initially a viscous behavior followed by a delayed, gradual, and slow elastic recovery. Thus, depending on the time period of force application, the plastic film displayed either pure elastic behavior or a combination of a viscous and elastic behavior. This is the universal characteristic of viscoelastic materials, namely, they either display elastic behavior in response to rapid deformations, or display a combination of viscous and elastic behavior in response to very slow deformations, or to deformations produced by forces applied for long time (27). Hair displays exactly the same behavior. When we deform it rapidly, as in a rapid head movement; or when we pass our fingers between the hair fibers, it behaves elastically, yet, the hair displays viscoelastic behavior when we deform it for long time. For instance, when we sleep with our hair bent or uncombed in an unwanted geometry, or in the morning when we wake up, our hair seems to stay bent and uncombed for long time, i.e., it does not recover immediately; but if we give it enough time it will remember its shape and recover gradually.

In summary, this remarkable mechanical behavior of hair is essentially due to the viscoelastic and shape-memory properties resulting from the disulfide crosslinked amorphous matrix and the keratin crystalline structure in the cortical cells. This behavior has been put in place by nature to provide an optimized assortment of mechanical properties for scalp protection and social communication—perhaps even as a part of the attractive mechanism between members of the opposite sex to facilitate propagation of the species.

The optimum mechanical and biological function of hair is thus achieved by a combination of an amorphous protein phase containing a gel and a non-gel structure, attached to the strong-coiled elastic keratin macrofibrils. For hair to maintain this optimum combination of softness, elasticity, strength, and shape recovery, it is necessary that we keep the biological activity of its proteins unchanged. We can achieve this, first, by helping hair to keep its amorphous

proteins moisturized so they are plasticized; and second, by keeping as long as possible the primary, secondary, and tertiary structure of the proteins in its native structure. We are all familiar with the fact that hair becomes hard and brittle when it lacks moisture, or with the fact that hair becomes weaker when its proteins oxidize or become brittle under the action of heat or prolonged UV radiation. We also know that hair becomes mechanically weaker after chemical treatments that we blithely apply in an attempt to look more beautiful, yet destroy strong hydrogen and covalent disulfide bonds that stabilize its tertiary structure, i.e., its crystalline structure (28, 29).

e. Water and moisture absorption/desorption by cortical cells

As in any other protein biomaterial, hair most of the time contains water, even at very low relative humidities. Water in general plays a crucial role on protein structure and function. It can be found in two states, namely, strongly bound and free or unbound water (30). In the case of hair, strongly bound water is critical for the conformation and mechanical stability of the helicoidal keratin fibrils that strand and form the macrofibrils in the cortical cells (31). This type of water is therefore critical in maintaining the mechanical properties of hair, and it can be found in hair even after it is subjected to zero relative humidity. This behavior is found even with a few water molecules that are strongly attached to protein functional groups and can only be removed from the hair by applying high temperatures close to its denaturation temperature (32). In fact, in the case of hair, denaturation of its proteins is caused by both losses of strongly bound water *and* breakage of disulfide bonds in the protein-amorphous regions.

In most cases, protein plasticization is ascribed to water molecules whose bond strength is weaker and can be broken by the movement of thermal motions of protein chains. This type of water molecule adsorbs onto the protein chains in multilayers and, at high moisture content, takes the form of bulk water. It is the water that causes swelling in hair and in other natural biopolymers (33–36). A great deal of information on the formation of water molecule multilayers and bulk water absorbed can be obtained by looking at the shape of the water absorption isotherm of a specific material. Figure 9 shows the water absorption isotherm corresponding to hair. One can see it is sigmoidal in shape and presents a hysteresis effect (37, 38). Namely, the amount of water content in hair depends on whether we moisturize it from a dried state or whether we dry it from a wet state. In very dry hair there are a few water monolayer or nucleating sites for multilayers to form by a process of condensation, therefore, the amount of water

absorption is low (line A). However, when hair is fully wet, water multilayers are already formed *inside* the hair. Under these conditions the desorption of water occurs by an evaporative process (line B).

Figure 9: Water absorption isotherm of hair (37).

In total, at 100% relative humidity hair absorbs up to approximately 30% of water, and even when moisture is also absorbed by the cuticle cells and the cell membrane complex, most of the moisture is absorbed by the cortical cells (19). Many other synthetic fibers also have the ability to absorb and desorb moisture.

Surprisingly, the process of water absorption/desorption by human hair has an ulterior natural function and it is not like any other ordinary process of moisture interaction with solid matter. It is part of the physiological phenomena used by nature to provide for hair softness, thermal regulation, and sweat transport. Hair interacts with moisture in ways that no other fiber can emulate. Incidentally, wool is the only other fiber that performs like hair, but this is so because wool is also a keratin fiber with a cellular and protein architecture similar to that found in hair. Hair and wool both have water properties that, in principle, appear antagonistic, i.e., they have a hydrophobic exterior that repels water and a hydrophilic protein interior that allows it to absorb and retain water depending on the environmental moisture conditions. These unique and paradoxical properties are not shared by other synthetic fibers. This analogical behavior is at the root of why so much research in developing cosmetic hair products begins in literature reviews of wool.

Because of their crosslinked structure, hair and wool have the ability to absorb large amounts of moisture and sweat without changing their mechanical integrity. The absorption of large amounts of water by hair occurs without the hair feeling wet and soaked and without excessive weakening of its protein

structure. These properties of keratin in hair contrast with those found in keratin of the skin. If we simultaneously submerge a piece of *stratum corneum* and a hair fiber in water we will observe, after a few hours, that cornoecytes in the *stratum corneum* swell without limit and lose their mechanical integrity. In contrast, the cortical and cuticle cells in the hair do not swell without limit and keep their integrity. Furthermore, as the amorphous protein matrix in hair absorbs and desorbs moisture it is able to release and gain heat depending on temperature differences between scalp and external environment. This particular behavior allows it to act as a heat buffer against rapid environmental temperature changes.

The effects of heat release upon moisture absorption by hair and wool, and their ability to keep warm surfaces is well documented (39). For instance, it is considered that if 1 kg of dry wool absorbs moisture from 40 to 70% RH it will release approximately 164 kJ (18, 32). If the wool is dried and absorbs approximately 35% of water it will release ~960 kJ of heat; this is as much heat as an electric blanket will release during eight hours. For these heat effects to take place, the wool or hair has to be dried and absorb moisture from low to higher moisture conditions. Then, as the wool or hair absorbs moisture the temperature will increase due to heat release. The water absorption isotherm of hair associated to this remarkable behavior was already shown in Figure 9; the points in this curve represent equilibrium states. The proteins in the amorphous matrix of cortical cells have various active sites for water adsorption. They are amino, carboxyl, and other hydrogen-bonding groups (40, 41). These proteins also act as nucleation centers for water multilayer adsorption. It has been reported that most of the heat released by wool or hair occurs when their hydrophilic groups absorb moisture in multilayer form at low relative humidities. At high relative humidities, moisture condensation and bulk water formation take place and there is less heat released.

3.3.1.5 DIFFERENT TYPES OF CORTICAL CELLS AND HAIR SHAPE

There are two types of cortical cells in hair; these are the ortho-and para-cortical cells (see Figure 10). Hair fibers from other mammals contain also a third type of cortical cells, namely, the meso-cortical cell, but this type of cell does not seem to be part of the human hair. There must be a reason for nature to have created two different types of cortical cells and confining them in two different

sections of the cortex within the same hair fiber. Existing data, whose interpretation is still controversial, suggest that the presence of ortho-and para-cortical cells is associated to the creation and stabilization of hair shape (42–44). It appears that by creating these two types of cells, nature can control hair shape by making it straight, curly, or extremely curly as a response to environmental adaptation. For instance, the cortical cells of hair fibers that are straight and limp have been found to be mostly of the para type. In contrast, the cortical cells found in hair that is curly are of two types, namely para and ortho, and their location in the cortex is such that they fill two distinct separate regions within the cortex of the same fiber (see Figure 10). Furthermore, the ratio of para to ortho type cells varies with the degree of curliness, i.e., the higher the content of ortho-cortical cells the curlier the hair is.

In spite of their differences, the ortho-and para-cortical cells are still made mostly of keratin filaments embedded in an amorphous matrix. However, because of their different packing density, the viscoelastic response of the hair section filled with para-cortical cells should be different from the section filled with ortho-cortical cells. Furthermore, the ortho-cortical cells seem to absorb less moisture than the para-cortical cells and this should result in a lower degree of water plasticization for this type of cell. This difference in moisture plasticization and viscoelastic response between the two inner sections of a single fiber has been evoked to explain the curliness enhancement seen in wavy and curly hair when moisturized.

Figure 10: Schematic representation of different ratios of ortho-and para-cortical cells in African, Caucasian, and Asian hair (60).

3.3.1.6 CUTICLE CELLS AND THEIR ROLE IN HAIR PROPERTIES

a. Cuticle cell structure and composition

As the follicle produces the cortical cells from stem cells, it also creates the cuticle cells. Like the cortical cells, the activity of the living cuticle cells is also highly specialized. In the process of differentiation they are instructed to become layered and flat in shape, with a final thickness of approximately 0.5 µm (see Figure 1). Subsequently, the follicle arranges them in stacks of 5 to 11 cuticle cells like shingles on a roof all around the cortical cells to create a strong protective shield. Their flat and layered structure organized in ordered stacks allows them to form the cuticle sheath. This form of cellular envelope acts as an effective shield that protects the cortical cells against friction, mechanical abrasion, impact, and other environmental stresses. It has been put there by nature to extend the life of hair to fulfill its function. Without the cuticle sheath around the hair fibers, the cortical cells will fray out and become rapidly damaged by friction. The cuticle sheath acts also as a gate to control incoming and outgoing light from the cortex to provide protection against radiation and color for aesthetic and social communication.

All of these important property/functions of the cuticle cells would not be possible without the unique architecture of their various layers and their specific chemical composition. For instance, the very top layer of a hair fiber, called the F layer, is made up of a fatty-acid chain, the 18-methyl eicosanioc acid or 18-MEA (see Figure 11). This fatty acid chain is attached covalently to an ultra-high sulfur-rich protein on the epicuticle surface (45–47). The attachment is made in such a way that the waxy part of the 18 MEA protrudes away from the epicuticle surface to provide the highly needed lubricity and hydrophobicity of hair fibers. Beneath the monomolecular layer of 18-MEA is the epicuticle followed by the exocuticle. These two layers, which are 120 and 250 nm in thickness, respectively, have the highest degree of sulfur content in the whole hair fiber (48).

Figure 11: Representation of F layer on cuticle cell surface showing 18-MEA attached covalently to the epicuticle (47).

The high sulfur content in these layers is testimony to the high degree of crosslinking bonds needed by the proteins at the surface so that the cuticle sheath can become hard and strong in order to resist mechanical abrasion. Then, beneath the exocuticle we find the endocuticle, this layer is composed of a non-cross-linked negatively charged protein, which is very susceptible to water swelling (49). The absence of crosslinked and crystalline proteins in this layer makes it highly deformable, very soft, and somewhat weak to mechanical stresses. It has been speculated that the soft nature of this layer allows it to act as a soft viscoelastic cushion to protect the hair against mechanical impact.

Below the endocuticle one can find the cell membrane complex (CMC), which is also the extracellular material used by the cuticle cells to bind and cement together. The structure of this cementing substance is very important because it not only glues cuticle and cortical cells but also plays a crucial role in the diffusion of moisture and other chemicals into the hair cortex.

The cell membrane complex is essentially composed of three layers: the upper beta layer, the delta layer, and the lower beta layer (see Figure 12). The beta layers are made of lipid chains arranged in palisades and attached on one side covalently to their immediate near protein network on the epicuticle. The other side of the lipid palisade is not covalently bound to the proteins in the delta layer; it is rather attached by physical forces also called dispersion forces. For this reason, many researchers consider this junction to be the weakest mechanical link in the whole fiber assembly (49–52). Cuticle and cortical cells fail at this junction when hair fibers are elongated to their breaking point and

when the cuticle cells chip away during dry combing. When wet, the cuticle cell fails rather at the soft protein zones in the endocuticle and not at the cell membrane complex (CMC).

Figure 12: Representation of cell membrane complex between cuticle cells (53).

The delta layer in the CMC appears to be made of proteins that are partially hydrophilic and partially hydrophobic. This layer is considered to contribute, in great part, to the diffusion of many liquids into the cortex. In the past, it was thought that the overall composition of the CMC, with its delta layer forming a sandwich between the two beta layers, was uniform all across the hair fiber. However, recent analyses made by C. Robbins and others appear to suggest that its composition changes depending on whether the CMC is cementing the cuticle cells, the cortical cells, or the cuticle/cortical cells interface (53) (see Figure 13). It has been proposed that the beta layers in the CMC gluing the cuticle cells are made of a monolayer of 18-MEA. As it was previously explained, this fatty acid is attached covalently to the epicuticle and physically attached to the delta layer. In contrast, the beta layers gluing the cortical cells are made of bi-layers of fatty acids, cholesterol, and ceramides, all of which are only physically attached on both sides. This important proposition suggests that the lipid of choice by nature to provide for high levels of hydrophobicity and lubricity to the hair surface is 18-methyl eicosanoic acid (18-MEA).

Figure 13: Representation of cell membrane complex between cortical cells of hair (53).

b. Viscoelasticity in hair and cuticle cells

The mechanical properties of the cuticle cells are just as important, if not more important, than those of the cortical cells for the function of hair. In fact, since hair is made of fibers whose length is comparably larger than their diameter, the fiber surface becomes predominant in controlling the mechanical properties of a hair assembly. Inter-fiber separation and air pocket formation for thermal regulation and aesthetic appearance are, therefore, mainly controlled by the mechanical behavior of the hair surface at the cuticle cells. Further, the integrity and mechanical stability of the cortical cells depends on the cuticle cells. Without the five to ten cuticle cells arranged in overlapping stacks to form the cuticle sheath, the cortical cells would rapidly collapse. Moreover, the surface of the cuticle cells not only has a high degree of hardness but also contains a lubricious fatty layer and is therefore very resistant to friction/abrasion. Hair fibers need this type of surface structure as they are constantly in motion, rubbing against each other.

Physical parameters relevant to these properties are the dynamic and static friction coefficients of the cuticle cells, the strength of the cuticle cell cement (CMC), and the Bending, Extension, and Compression Modulus of the cuticle cells. Unfortunately, data on the various mechanical modulus of the cuticle cells is scarce. Experimental studies carried out by various researchers have revealed, however, that the mechanical behavior of cuticle cells is not elastic but, as in the

case of the cortical cells, their behavior is also viscoelastic (54, 55). This is not surprising since the proteins making the various components in hair are biopolymers and, therefore, the overall behavior of each one of these components is also viscoelastic.

The phenomena of cuticle cell lifting and buckling produced by various environmental, mechanical, and thermal stresses, and the time it takes to recover from these deformations, are proof of cuticle cell viscoelasticity (56). Lifting and buckling of the cuticle cells occurs often in hair when subjected to continual elongation during combing, and also by thermal stresses after blow-drying or hot iron applications. Cuticle cell cement breakage and buckling are two of the most common manifestations of viscoelastic material mismatch between the various layers of the cuticle cells. When hair fibers are stressed, either thermally (by rapid compression due to water evaporation), or mechanically during excessive tensile elongation, the internal components of the single cuticle cells, i.e., the epicuticle, exocuticle, endocuticle, and cell membrane complex, do not respond in the same manner. This causes an excessive accumulation of shear stresses at their junctions and, consequently, the weakest link within the cuticle cell fails. Depending on moisture conditions, the endocuticle or the cell membrane complex fails, causing either cuticle cell buckling or breakage (52).

Cuticle cell damage in the form of cement breakage and buckling is commonplace in most people and it is significantly increased by various damaging hair treatments (54–60). This type of hair damage is almost absent in hair sections close to the fiber root and it is commonplace at its tips. Thus, a strong possibility exists that the “cement” becomes weaker by various environmental oxidative stresses during the life of a hair fiber. Gradual oxidation of the various cuticle cell layer components and their junctions will make them more prone to breakage by mechanical extensions during grooming.

Figure 14a shows a typical image of hair near its tip taken from a female subject with long hair (60). The same type of cuticle cell damage can be produced in virgin hair in the laboratory after subjecting it to large elongations and to thermal stresses (see Figure 14b). A very interesting aspect of cuticle cell buckling is that the deformations causing it can be either viscoelastically reversible or irreversible. For instance, it has been found that most of the buckling deformations produced during a hair-damaging process are reversible, i.e., the buckled cuticle cells can actually recover their original shape if enough time is allowed for recovery. There is, however, depending on the damaging process, a fraction of cuticle cells that cannot recover their shape and remain

permanently and irreversibly deformed (61).

It should be pointed out here that cuticle cell buckling always entails breakage of the “cement” or cell membrane complex (CMC). This is true regardless of whether the deformations in them are reversible or irreversible. In most cases, once the cuticle cells have undergone buckling their mechanical integrity is compromised. For instance, simple hair-strand swelling by water absorption and the resulting stresses are not capable of inducing cuticle cell lifting and buckling in virgin cuticle cells. Yet, after they undergo buckling, and after the cells have recovered from their deformations, they can be easily lifted and buckled again by simple water imbibition and resulting swelling. Studies have shown, however, that in certain cases the cell membrane complex by itself may have the ability to partially recement and re-glue the cuticle cells (61, 62). For instance, experiments have shown that, if deformed and lifted cuticle cells whose cement is broken are allowed to recover closing their gap, they will not lift again when immersed in water. In many cases the previously buckled and recovered cells will only buckle again when the levels of mechanical stresses are similar to the ones that initially produced cell lifting. This observation seems to indicate that, under certain conditions, the “cement” is able to partially recement the cuticle cells.

Figures 14a and 14b: SEM pictographs of cuticle cell buckling in hair as follows: (14a) as it appeared in a long hair of a female subject, and (14b) produced in the laboratory by mechanical stresses in an undamaged hair fiber (60).

c. Water and moisture absorption/desorption by cuticle cells

In the previous paragraphs we have pointed out that moisture absorption by the cortical cells has beneficial effects for the function of hair; among these benefits are scalp/skin temperature buffering, moisture transport, and a large contribution

to softness/plasticization of hair fibers. We also pointed out that water is the main protein plasticizer, and we came to the conclusion that moisture makes hair softer because it plasticizes the amorphous protein in the cortex. An observation that is often ignored by many researchers studying keratin fibers is that the cuticle cells also absorb moisture and, most importantly, that their mechanical behavior is very sensitive to moisture. The strongest evidence of this sensitivity is the effect that moisture has on cuticle cell recovery from deformations that were caused by stress buckling. Figure 15a shows an SEM picture of a hair fiber whose cuticle cells underwent buckling deformations after the fiber was subjected to a mechanical elongation of about 15%. The same hair fiber with its cuticle cells recovered is shown in Figure 15b, where recovery of the buckled cuticle cells took place after the fiber was immersed in water absorption (61, 64). Likewise, Figure 16a shows a micrograph of deformed and buckled cuticle cells produced in hair by blow-drying in the presence of water and low-molecular-weight oils (58); while in Figure 16b the same hair fiber can be viewed with its cuticle cells recovered after they were allowed to absorb moisture. The pictures were obtained by optical microscopy using the technique of patterns of light interference analysis described in more detail in the following paragraphs.

Figures 15a and 15b: SEM micrographs of cuticle cell buckling before (15a) and after water immersion (15b). Both micrographs correspond to the same spot in the hair fiber. As a point of reference, observe the elongated deep crack in the top section of the hair fiber (60).

Experimental observations made on those cuticle cells as depicted in Figures 16a show that their deformations do not recover if they are left alone for a good period of time at normal temperature (25°C) and under moisture conditions (53% RH). The experiments showed, rather, that the deformed and buckled cuticle cells recover only when moisture condenses on the cuticle cells, i.e., when the hair surface is above the dew point (65). These simple observations indicate the following: a) that cuticle cells need to absorb liquid water and not gaseous water molecules to recover by water plasticization and, b) that protein

moisturization in the cuticle cells only occurs when multilayer adsorption occurs at protein chains by moisture condensation.

Figures 16a and 16b: Optical micrographs of buckled cuticle cells observed in a hair fiber blow-dried in the presence of low-molecular-weight oils by using the LIP technique (54). Figure 26a represents the state of the cuticles after the hair fiber was blow-dried, and Figure 16b shows the cuticle cells after the hair was immersed in water for a period of one minute (60).

Moisture absorption by the cuticle cells is thus crucial for the cells to recover from deformations and to comply mechanically with the deformation of the cortex and the whole hair fiber. Just as in the case of cortical cells, cuticle cells are also able to perform their beneficial function in hair if they are plasticized by water, i.e., "moisturized." It is important to mention here that the subjective perception of "hair dryness" is de facto associated to a lack of moisture in the cortical cells. However, studies have shown that this is an incorrect conception since hair swatches that were equilibrated at high relative humidities seemed to obtain higher "dryness perception" scores than those equilibrated at low relative humidities (66). An explanation of these contradictory facts has already been offered by some scientists. They have proposed that roughness on the hair surface, and not lack of moisture in the cortex, is what creates the perception of dryness in hair (66). Moisture content in the cuticle cells should, therefore, have a stronger correlation with the sensation of hair dryness.

d. Optical properties of the cuticle cells

Another important property of the cuticle cells is their optical set of properties. All the various layers composing the cuticle cells are transparent. When white light strikes a hair assembly the first component it encounters is the cuticle sheath. The main physical property that determines how a transparent material interacts with light is its index of refraction (IR). The IR of the cuticle sheath has

been reported to be ~1.53 (67); the IR of each cuticle layer is not known, but because each one has a different composition and architecture, it is expected that its behavior will be somewhat different. The behavior of white light striking the cuticle cell—just as in the case of other transparent materials—thus, will be dependent on the IR of each layer. Its value will thus determine how much light is reflected, refracted, and absorbed by the cuticle cells. Reflected light can be of two types, specular or diffuse. If the reflected light is specular it will give rise to shine; if it is diffuse it will give a matt and dull appearance to hair. Light that is refracted passes through the cuticle cells and reaches the cortex, where it interacts with the pigments of melanin. There, a certain wavelength component of the light will be absorbed and the remainder of the light, which will not be white any more but colored, will be reflected back into the cuticle cells. The light will pass, then, throughout the cuticle cells and will appear to the eye as hair color (see Figure 17). If part of the light diffracts, penetrates into the cortex, and is absorbed by the melanin granules, the hair color will appear shiny and black, brown, or blond depending on the type of melanin. As it will be seen later, brown and blond colors are produced by different amounts of a brown melanin granule called eumelanin.

The condition of the cuticle cells thus determines the optical appearance of the hair assembly. If the cuticle cell cement is broken and the cuticle cells are lifted, light will not be properly transmitted to the cortex, and neither will it be specularly reflected. Rather, the light will be scattered and diffused and the hair will partially lose its shine and color, thereby, appearing dull and lifeless. Recently, it has been found that, either, when the cuticle cells are lifted, or whenever there are micro-pockets of air within the cuticle cell layers, the cuticle cells produce colorful microscopic light-interference patterns (LIPs) (see Figures 18a and 18b) (56). It is important to mention here that the vivid colors found in insects, butterflies, birds, and also in some mammals str created by such light-interference phenomena. These colors are usually very strong and they are not created by subtraction of colors from white light due to absorption by pigments. Rather they are created by the same mechanism used by soap bubbles to create color—a phenomenon based on the constructive and destructive interference of light (see Figure 19). This phenomenon is also known as iridescence, and the colors are called structural colors (68, 69). In the case of hair, if the interference colors produced by lifted cuticle cells could be made coherent at the macroscopic level, they would create strong and vivid colors.

Figure 17: Diagrammatic representation of light interacting with hair showing (a) total reflection of colors, and (b) light reflection plus diffraction and absorption by melanin granules.

Unfortunately, the lifted cuticle cell areas containing air in their layers creating these strong LIPs are very small, and light-scattering edge effects dominate. In addition, because of the small size and discontinuity in the lifted cuticle cells, the strong interference colors are not coherent at the macroscopic level. Consequently, their final effect to hair appearance is rather deleterious. However, the weak patterns of iridescence produced by the layered structure of undamaged cuticle cells certainly will contribute to the final optical appearance of hair. Colored light coming from the melanin in the cortex will thus combine with colored light produced by the weak iridescent patterns of virgin cuticle cells, and both, just as in the case of cuticle cells of some mammals, should produce the final hair optical properties. Thus, the weak iridescence patterns of virgin cuticle cells contribute to the unique color properties of undamaged hair.

Figure 18: Micrographs showing lifted and buckled cuticle cells on the same fiber by SEM (left), and by optical microscopy (right) using the LIP technique. Lines and circles in the pictures identify same features (56).

Figure 19: Diagram of lifted cuticle cells describing formation of light interference patterns by the phenomenon of thin-film light interference (56)

The color and shine enhancement often seen in hair when wet is a typical example of improved hair color perception due to changes in the IR of the cuticle sheath. Color enhancement in wet objects that absorb water can thus be explained by two mechanisms. The first is by the decrease in light scattering due to water filling of the otherwise empty pores containing air. The second is color and shine enhancement in hair by moisture absorption, also due to changes in the IR of the endocuticle, which enhances the phenomenon of iridescence. Polydimethylsiloxane polymers, oils, and some other high-molecular-weight polymers can also produce similar effects—as long as they are able either to penetrate into air gaps at the cuticle sheath or to smooth the cuticle cell surface to eliminate diffuse scattering.

e. The medulla cells

The medulla in hair refers to a region of very low density located at the center of a hair fiber (11). It is considered to be porous, irregular in shape; and, in human hair, in most cases, it is not continuous all along a single hair fiber. The regions of low density can be detected either by scanning electron microscopy or by optical microscopy (see Figure 20). In Figure 21, we can see a photograph showing the discontinuous presence of medulla along the hair fiber by which the hair was analyzed by transmission using optical microscopy (70). Not all hair fibers have medulla, but it is frequently found in thicker hair. Analyses have shown that, even in the case of thick hair, hair fibers from the same head may or may not have medulla cells. The medulla region is made of cells that are very different in structure to the cortical and cuticular cells; they are large and cuboidal in shape, and often, but not always, they are very porous. The structure, composition, and role of the medulla cells are not very well known. Because of

their porous structure, the medulla cells are filled with air and it has been speculated that this cell-air system contributes to increase the hair's ability to provide thermal insulation. The medulla cells have also been reported to have a strong impact on hair optical properties (71).

Figure 20: Micrograph of hair showing medulla region in hair (60).

3.3.1.7 MELANIN PIGMENTS IN HAIR

The melanin pigments in hair are made of very interesting molecules that play a crucial role in the function of hair. They act as free radical scavengers, antioxidants, UV light absorbers, heat radiation absorbers, and also as gamma rays absorbers (72–74). Melanin pigments not only protect the proteins in hair against oxidation and UV damage, but also help to protect the scalp from excessive harmful UV and heat radiation. They also provide color to hair for aesthetic and social communication. The protective action of melanin pigments is so important that nature does not use melanin only in hair, but also in the neurons of the brain as well as in the cells of eyes. Melanin has been found to provide important protection effects to the eyes; among these are the following: photoprotection, vision enhancement, decreases in the risk of cataract formation, and a lower risk of macular degeneration in the retina (73, 74).

Figure 21: Micrograph showing discontinuity of medulla region along a hair fiber (60).

Melanin granules in hair are approximately 0.8 µm in diameter (see Figure 22). They are polymeric in nature and depending on their type they differ chemically. The various chemical moieties forming the melanin polymer are 5,6-dihydroxyindole (DHI) and 5,6-dihydroxyindole-2-carboxylic acid molecules (75, 76). A description of their composition is given in Figure 23. Melanin granules isolated from hair or skin display brown, black, green, and yellow colors.

There are many types of melanin and they can be grouped into two main types, namely, eumelanins and pheomelanins. Eumelanins can be further divided into brown and dark eumelanins. Brown eumelanin is common in people with lighter or brown color while dark melanin is typical of people with dark hair. Gray hair is caused by the absence of melanin in general while blond hair is produced by low amounts of brown eumelanin. Red hair contains mainly pheomelanin as pigment, which is also found in small amounts in skin together with eumelanin. The melanin granules are made in the follicle not by the cortical or cuticular cells, but rather, by specialized cells called melanocytes. Once the pigment granules are made, the melanocytes get instructions to excrete them and pass them into the cortical cells, where they are incorporated by phagocytosis (76, 77).

Figure 22: SEM micrograph showing physical aspect of melanin pigments in hair SEM (72–75).

Figure 23: Schematic representation of melanin composition (75).

3.3.1.8 HAIR FUNCTION

As discussed in the previous paragraphs, the sequences of amino acids constituting the primary, secondary, tertiary, and quaternary structures in the proteins of hair are optimized so the fibers are capable of fulfilling their biological functions. Other biological substances in hair—such as lipids, polysaccharides, and complex polymeric molecules—are found in the cuticular cement and in the melanin pigments. These are also carefully structured in the hair cells to fulfill a specific function. This optimization of composition and structure in the cells occurs so that hair can, finally, serve its biological functions of temperature buffer by absorption/desorption of water, protection against harmful environmental radiation, thermal and mechanical insulation, and aesthetic agent in social communication. Hair with an undamaged structure is apt to perform its biological function, and it is not coincidental that undamaged hair is also aesthetically and cosmetically appealing.

3.3.1.9 THE FOLLICLE

As we have stated earlier, the follicle is the smallest organ in the body, and it is there where hair fibers are produced (see Figure 3). Also acknowledged previously, there is one single follicle for each hair fiber. This minute organ is essentially composed of various biological units, namely: bulb, dermal papilla, bulge, and external and internal root sheath (78). With these key basic units, follicles are able to produce and assemble hair cells to form hair fibers. There are between 100,000 and 150,000 follicles in a normal scalp, distributed on its surface in the form of clusters of three or four hair follicles (see Figure 24). Evidence suggests that the number of hair follicles is constant throughout one's life, so the number of hair fibers on a scalp will, at least, while one is alive,

remain constant. The hair follicle, with all its basic internal units, regenerates itself approximately every four to six years. At each regeneration cycle, the hair fiber that has been produced falls out, and a new one starts to grow.

Figure 24: Clusters of various follicles in scalp (60).

a. Different zones in the follicle

All cells forming a hair fiber are made in the follicle from stem cells (79–81). The manufacture of hair cells involves a very well-organized process of stem cell preparation, shaping, and assembly in a way that is akin to a car assembly line. These various processes occur from bottom to top of the follicle in three main zones; namely: a zone of cell proliferation; a zone of gene expression and differentiation, and, finally, a zone of cell hardening or keratinization (see Figure 3) (11).

Each zone within the follicle has specific tasks crucial for hair production. At the bottom of the follicle is the first zone, and it is constituted by the dermal papilla and basal membrane. It is in this zone where epithelial stem cells that descend from the bulge are gathered to receive instructions from the dermal papilla to proliferate by mitosis. Moving towards the tip, in the next contiguous zone, the cells obtain instructions also from the dermal papilla to become differentiated into cuticle, cortical, and medulla cells. During this process they are packed and glued together, forming a cylindrical shape. Moving further towards the tip in the following third zone, located in the middle portion of the follicle, the hair cells are instructed to undergo apoptosis and become hard through a process of keratinization. In this zone, proteins in the cortical and cuticle cells become crosslinked to attain their final optimized, mechanical, thermal, and physical properties. In the zone of keratinization the hair reaches its final form and emerges from the scalp.

Just as in a car assembly line, where total production is controlled by external demands and internal constraints, there has to be a very well-coordinated process of communication within the follicle itself and with other body glands to

successfully produce hair. For a period of approximately four to six years each hair follicle is instructed to keep its key components active making hair. The new portions of hair created in the follicle push out upper sections of the fibers and the hair grows. At the end of the sixth year of activity, the follicle gets instructions from the body's glands and genetic system to cease and stop the production of hair. The ancillary machinery in the various zones of the follicle is then shut down, and the three zones of the follicle become completely inactive. Subsequently, the key components of the follicle are dismantled and discarded as they are pushed out by new ones being formed underneath. In this way, the old grown hair fibers, together with their inactive follicle units, are pushed out from the scalp and the hair fibers fall out. The new components form a new follicle with new zones of cell proliferation, gene expression/differentiation, and cell keratinization, and a new hair fiber grows.

b. Life cycle of the follicle

From the time of its inception until it recedes, the regenerated follicle has a life cycle characterized by three different phases, namely: anagen, catagen, and telogen (see Figure 25) (82). In the anagen phase, the assembly line activity of the hair follicle is invigorated and has its maximum efficiency preparing and assembling cells into fibers. It is at this stage that the hair fibers in the three zones of cell creation, differentiation, and keratinization are continuously assembling and growing. An intensive production of cuticle and cortical cells via stem cell mitosis characterizes this stage. The produced cells are continuously shaped and assembled into hair fibers by instructions from the dermal papilla in coordination with other body glands. For instance, it is well known that the growth rate of hair is strongly dependent on certain hormones and that it is used by nature as a tool of social communication to assert gender differentiation. During the anagen phase most of the hair fibers thus acquire their main physical, mechanical, thermal, and optical properties. The overall characteristics of hair fibers are therefore dependent on nutritional and hormonal variations affecting this stage of follicle development. Then, in the catagen phase, which lasts only two to four weeks, the follicle lowers its cell production and a large part of its cells undergo apoptosis. In the telogen phase, which lasts only from two to three months, the inactive parts of the follicle are pushed out and the old hair falls out.

New research has actually shown that the activity of the follicle is even more complicated than described in the three stages mentioned above. Some researchers have already proposed the existence of various substages for each

one of the three main phases (83). There are two main reasons behind these proposals:

Figure 25: Life cycle of the follicle: anagen, catagen, and telogen (60).

namely, a) each stage has very well-differentiated activities that can be further divided, and b) it has been found that at the end of each stage there are already preparatory signals taking place for the next stage. In fact, the appearance of new follicle components producing a new hair fiber starts in the follicle even before the older fiber is pushed out; so the anagen phase of a new growing hair fiber in some cases overlaps with the telogen phase of a hair that is going to fall. Thus, some of the processes controlling the formation of new hair fibers and the shedding of old ones seem to overlap between phases. This process can easily be perceived in the picture of human scalp shown in Figure 24, where it can be seen that in certain areas there are two hair fibers emerging from the same follicle.

All processes taking place in the follicle, whether they occur in the anagen, catagen, or telogen phase, or in any of their substages, need to occur in synchrony. Their occurrence involves the timely interaction and participation of a large number of biopeptides, enzymes, and other biological factors that act as regulators, communicators, and controlling agents for the production of stem cells, cells division, cell apoptosis, keratinization, *etc.* Furthermore, the maintenance process of the hair shaft, after it has emerged from the scalp in all its length, is partially executed by the biological activity of the follicle. Sebum and enzymes are released from the sebaceous glands in concert with the follicle to maintain the integrity of the hair shaft.

Hair diseases, hair defects, or mechanical weaknesses in hair fibers are caused by internal or external factors that interfere, block, change, or damage the

various biological processes involved in normal hair growth and hair maintenance. Traction alopecia, androgenetic alopecia, chemical alopecia, trichorrhexis nodosa, *etc*. are all hair ailments caused by some sort of internal or external interference. It has recently been discovered that the follicle is the target of major hormonal pathways, and that the follicle and sebum glands, both together, referred to as the pilosebaceous unit, can also act as a peripheral hormone-producing unit for a wide range of steroid hormones, neuropeptides, and neutrophins (84). Thus, proper growth of new hair fibers and shedding of old ones require no obstruction or interference with the biochemical substances involved within the follicle. Any internal or external factor interfering with the function of these biochemical substances will cause some sort of malfunctioning or disease in hair growth.

Acknowledgments

The author would like to thank Linda Foltis for her helpful discussions and support during the writing of the manuscript. Thanks also to Ashland, Inc. for providing the opportunity and resources to carry out this task. The editor-in-chief, Meyer R. Rosen, would like to thank Manuel Gamez-Garcia and Linda Foltis for an extraordinary, in-depth, diversely technical exploration of the physical and chemical nature of hair. We believe that knowledge at this depth will generate new ideas for ingredients and mechanistic approaches that address consumer needs in an aging society, which are strongly needed as hair and its appearance, both in women and men, is a major factor in the look-good, feel-good search occurring during the inevitable(?) aging process.

AN OVERVIEW OF HAIR FOLLICLE ANATOMY AND BIOLOGY

By

Paul Mouser Ph.D.
Ashland, Inc.,
Ashland Specialty Ingredients,
Bridgewater, NJ, United States

ABSTRACT

Since ancient times, the human hair has been an attribute for health, youth, and attractiveness as it plays a vital role in people's self-perception [(1)]. As a result, changes in the appearance of hair such as hair loss, hair thinning, and premature graying often cause psychological distress to the affected individuals.

Hair is produced by a multicellular entity; the **hair follicle**. The hair follicle is one of the most fascinating and dynamic organs of the human body and, unlike the hair itself, which is composed of dead keratinocytes, hair follicles undergo a process of regeneration that controls the production of the hair fiber. One can distinguish between three main types of hair follicles: the **lanugo**, the **vellus**, and the **terminal hair follicle**:

- **Lanugo hair** is very fine and normally shed *in utero*, or during the first weeks of life.
- **Vellus hairs** are very short, nonpigmented, nonmedullated hairs found all over the body surface.

Terminal hair is the large, and usually pigmented and medullated hair that is predominantly found on the scalp. It is estimated that humans have around 5 million hair follicles, of which 80,000 to 150,000 are located on the scalp. Scalp hairs grow at a rate of 0.3 to 0.4 mm per day [(2)]. **No additional follicles are produced after birth**, although the size of the follicles and hairs can alter with time, primarily under the influence of androgens. In pubic, axillary, and beard regions, androgens stimulate the conversion of vellus to terminal hairs, whereas

in frontal scalp regions of genetically predisposed individuals, androgens trigger miniaturization of hair follicles via conversion of terminal to vellus hair follicles [3].

The most unique feature of hair growth is its cycle. Hair follicles undergo repeated cycles of anagen (growth), catagen (degeneration), and telogen (quiescence). During anagen, hair follicle stem cells sustain the steady production of matrix cells in the hair bulb. These proliferate several times and terminally differentiate into the companion layer, the inner root sheath, and the hair shaft.

Unwanted hair loss is a common problem and is suffered by much of the world's population in both women and men. The condition is characterized by premature hair loss and excessive hair shedding. The process is caused by an interruption in the normal hair growth cycle, which can lead to the development of baldness with insufficient replacement of hairs in human scalp. This can have negative effects on an individual's self-esteem and thus products that claim to be useful for treating hair loss target a steadily growing, multibillion-dollar market worldwide.

The field of human follicle biology is progressing rapidly largely because of technical advances in molecular and cellular biology as well as sophisticated cell culture techniques. This chapter reviews the structure of hair, the biological processes occurring during the hair growth cycle, and the changes that occur with hair aging.

3.3.2.1 HAIR FOLLICLE STRUCTURE

The hair follicle is a three-dimensional tube, composed mainly of epithelial cells,

which protrude down through the epidermis and dermis of the skin (Figure 1).

Figure 1. Human scalp tissue isolated from the scalp. Hair follicles protrude down through the epidermis and dermis of the skin (photo kindly provided by Dr Claire Higgins)

Hair follicles vary considerably in shape and size, depending on their location, but they all have common architecture. Anatomically, the hair follicle is most commonly described when it is in the mature anagen stage (Figure 2A). The mature anagen follicle can be divided into an upper permanent portion (infundibulum and isthmus), which does not cycle, and a lower part (bulb and suprabulbar), which is remodeled in each hair cycle. The infundibulum is the opening of the hair canal to the skin surface, and the isthmus is the permanent middle section extending from the sebaceous duct opening to the point of arrector pili insertion. The lower isthmus also contains the bulge region (Figure 2B), which is a region of functional importance as it is in this location that a reservoir of stem cells reside. Stem cells are unique, as they have the capacity to generate all the differentiated cell types within tissue and to self-renew in order to replenish their pool. Earlier studies have demonstrated that all epithelial layers within the hair follicle and hair originated from bulge cells [4, 5]. Hair follicle stem cells therefore appear to be responsible for regenerating the hair follicle in each cycle. Up until recently the location of the bulge in human follicles was unclear. By contrast with the bulge in rodent follicles, human follicles are not morphologically distinct. However, identification of unique bulge markers in the human follicle has enabled the human anagen bulge to be defined as a distinct region [6, 7].

Figure 2. Structure of human anagen hair follicle. (A) Longitudinal section of a human scalp hair follicle showing the permanent (infundibulum and isthmus) and cycling (suprabulbar region and bulb) components of the hair follicle. (B) High magnification image of the isthmus. The dashed square indicates the approximate location of the bulge. (C) High magnification image of the bulb showing the outer root sheath (ORS), inner root sheath (IRS), matrix zone (M), dermal papilla (DP) and connective tissue sheath (CTS). (D) Schematic drawing illustrating the concentric layers of the ORS, IRS and shaft in the bulb. Current Biology 19, R132-R142 2009 ©2009 Elsevier

The anagen bulb (Figure 2C) is one of the most rapidly dividing tissues in the body. The bulb represents the hair shaft factory; it contains the proliferating matrix keratinocytes and pigment-producing melanocytes (matrix zone). The hair matrix keratinocytes move upwards and differentiate into the hair shaft, as well as into the inner root sheath; the melanocytes transfer pigment into the developing hair keratinocytes to give hair its color [8]. These cells are supplied by the pluripotent stem cells existing in the bulge. The hair bulb surrounds the dermal papilla, which comprises a group of specialized cells (dermal papilla cells) with important inductive properties. The dermal papilla is believed to be one of the most important drivers that instruct the hair follicle to grow, and dictates hair bulb size, hair shaft diameter, length, and anagen duration.[9] The dermal papilla is known as the “conductor of the orchestra” or “command center,” and is an essential source of growth factors (keratinocyte growth factor, bone morphogenetic protein, hepatocyte growth factor, insulin-like growth factor, stem cell factor), all of which are critical for hair growth and melanogenesis [8]. Surgical removal of the dermal papilla and the lower dermal

sheath prevents hair growth, which indicates the importance of these specialized cells as the key signaling center in hair follicles [10]. Interestingly, dermal papilla cells from balding scalp have both higher levels of androgen receptor (AR) and type II 5-alpha reductase, which converts testosterone to dihydrotestosterone (DHT) [11]. DHT can induce dermal papilla cells to secrete factors including transforming growth factor beta 1 (TGFb1) and DKK-1 that inhibit keratinocyte growth [12, 13].

The hair shaft (Figure 2D) is divided into the hair cuticle on the outside and both the cortex and medulla in the center. The cells that make up the hair shaft are known as trichocytes, which are terminally differentiated hair follicle keratinocytes. The hair shaft cuticle consists of overlapping cells that are arranged like shingles pointing outward and upward. The hair shaft cortex, the bulk of the hair shaft, is composed of hair-specific keratin filaments and keratin-associated proteins with melanin produced by melanocytes in the matrix region [2]. The hair shaft medulla, the central part of the hair shaft, is composed of large, loosely connected keratinized cells with large intercellular air spaces. The hair shaft is surrounded and supported by the inner root sheath (IRS), the companion layer, and the outer root sheath (ORS).

The IRS consists of three distinct layers: the cuticle, Huxley's layer, and the Henle's layer (Figure 2D). The IRS cuticle layer adjoins the cuticle of the hair shaft and anchors the hair shaft to the follicle. IRS keratinocytes produce keratins and trichohyalin that serve as an intracellular "cement" giving strength to the IRS to support and mold the growing hair shaft, as well as guide its upward movement [8].

The ORS surrounds the IRS and is continuous with the basal layer of the epidermis. Distinct from the other epithelial components, the ORS does not generate by upwards growth from the matrix zone, but rather directly from the stem cell bulge. The bulge region of the ORS is located just below the sebaceous gland and at the insertion site of the arrector pili muscle. Stem cells leave the bulge in the ORS and migrate toward the matrix zone, where they begin to proliferate and subsequently differentiate into new hair shafts [14].

Hair follicles grow in an oblique angle towards the epidermal surface. This angle can be varied by the contraction of a bundle of muscle, collectively called the arrector pili muscle (APM). The APM is under adrenergic control and thus, in situations of cold temperature and emotional stressors, it gives rise to the interesting phenomenon of involuntary contraction resulting in the hair standing up!

3.3.2.2 HAIR FOLLICLE CYCLING

Hair growth and loss in humans is controlled by a specific follicular cell cycle (Figure 3) that includes three major stages [9]:

- growth and differentiation (**anagen**)
- regression and apoptosis (**catagen**) and
- rest (**teleogen**)

Additional phases recently discovered include exogen, in which the fiber is actively shed [15], and kenogen, when the follicle is empty [16].

Figure 3. Hair Follicle Cycle. The different stages of the adult hair follicle are divided into three main categories known as anagen, catagen, telogen, which continually cycle throughout the life of the follicle. During anagen the matrix cells of the bulb (red) rapidly proliferate and differentiate to produce the hair fibre and layers of the inner root sheath. The hair follicle enters catagen which is characterized by apoptosis of the epithelial cells, and the formation of the club fiber. The dermal papilla (blue) moves up to the base of the permanent section of the follicle, in close proximity to the bulge (green). A resting phase known as telogen then occurs before the renewal of a subsequent anagen phase. Exogen describes the removal of the remaining club fiber which typically occurs close to the time of renewed anagen onset. Seminars in Cell & Developmental Biology 18 245-254 2007 ©2007 Elsevier

Hair follicle cycling is driven in response to continuing molecular interactions between the dermal papilla and the epithelial components of the follicle [17, 18].

The duration of the different growth phases depends on the type and localization of the hair follicle. Scalp follicles stay in the anagen stage for two to six years and produce long hairs, whereas eyebrow or eyelash hair follicles do so

for only one to three months and produce short hairs. An in-depth description of eyelash hair follicles may be found elsewhere in this book. What determines the clock mechanism and the duration of anagen in individual hair follicles is not known, although one candidate for consideration is the circadian clock, a molecular oscillatory system [19, 20].

Following morphogenesis, the hair follicle enters the regression phase (catagen). The catagen stage lasts approximately two weeks, during which time the hair fiber ceases to grow. During the catagen stage, cells located in the lower portion of the hair follicle undergo programmed cell death (apoptosis). The hair follicle shortens and the hair bulb loses its internal and external sheaths. During this process the hair follicle acquires a club-shaped end and is subsequently referred to as the "club fiber." Additionally the dermal papilla condenses, moves upward beneath the hair follicle bulge, and halts its activity. Follicular melanogenesis also ceases during this stage. Catagen has been suggested to occur as a consequence of decreased expression of anagen maintaining factors, such as insulin-like growth factor 1 (IGF-1), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), and increased expression of cytokines promoting apoptosis, such as TGFb 1, interleukin-1alpha (IL-1a), and tumor necrosis factor alpha (TNFa) [21].

Upon catagen completion, hair follicles enter a resting stage (telogen) for an average of three months. In the telogen stage, the hair follicle has decreased to about half of its previous size and the stem cells are thought to be quiescent. However, by the end of the telogen stage, hair follicle stem cells become activated by Wnt and TGFb signals from the dermal papilla and form a new hair follicle [22–24]. Anagen involves the complete regrowth or regeneration of the lower, cycling portion of the follicle, i.e., the hair shaft factory. The cross-talk of dermal papilla with neighboring matrix cells results in the maintenance of hair fiber production (i.e., the hair continues to grow). Two secreted molecules that have important roles in hair follicle cycling are IGF-1 and bFGF. Both are produced by the dermal papilla, and their receptors are found predominantly in the overlying matrix cells [25].

Sometime after new shaft production begins, the club fiber is shed [26]. The term 'exogen' has been introduced to identify the hair fiber shedding event as a separate process during hair follicle cycling [15]. Shedding of 100–150 hairs per day is normal [2]. Previously, hair fiber shedding was believed to be passive, but recent research suggests that shedding is an active and highly controlled process [15, 27, 28]. Empty hair follicles, after shedding of the club fiber, but before the onset

of renewed anagen, are in a stage called “kenogen.” Kenogen can be observed in healthly skin, but the frequency and duration are significantly greater in individuals with androgenetic alopecia [16].

In addition to hair follicle tissue modeling, skin innervations and vascular networks also undergo substantial changes with the progression of the anagen stage [17, 29]. Perifolicular vascularization is significantly increased during anagen. It correlates with the up-regulation of the expression of vascular endothelial growth factor (VEGF) mRNA, a potent angiogenic growth factor, produced by keratinocytes of the outer root sheath [8].

Each follicle can undergo repeated cycles until it eventually dies or miniaturizes to give rise to a vellus hair [30, 31]. **Disturbances of hair follicle cycling lie at the heart of most hair growth disorders, and have dramatic effects on visible hair growth and shedding**. For instance the most common alopecia, *androgenetic alopecia*, produces a patterned baldness involving a reduction in the percentage of scalp hair follicles in anagen, a reduction in the anagen growth phase duration, and a corresponding increase in the percentage of hair follicles in telogen and an increase in the duration of telogen. These alterations (in combination with a shift in the exogen phase from primarily occurring in early anagen to initiation primarily during telogen) result in thinning hair coverage [32, 33]. The most effective therapeutic strategies for hair loss therapy inhibit catagen development so as to prolong anagen, to induce anagen in telogen follicles, and/or to inhibit exogen [34].

3.3.2.3 AGING OF THE HAIR FOLLICLE

While consumers are increasingly concerned with diminishing the signs of aging, especially the aesthetic of hair, addressing the cellular mechanisms behind them represents a decisively new direction in hair care strategies. Like all biological systems, the hair follicle also undergoes an aging process. This process is not only characterized by loss of pigmentation, but changes in growth characteristics that include decreased hair follicle density, increased number of telogen hairs, a decrease in the diameter of hair shafts, and slower hair growth rates [35–38].

The color of hair mainly relies on the presence or absence of melanin pigment. Two types of pigment can be produced by the hair follicle. The first type is eumelanin, which is the pigment in brown-black hairs, while the second type is pheomelanin, the pigment in red-blond hairs. Melanin is produced by the

melanocytes, and is the result of a complex biochemical pathway (melanogenesis) with tyrosinase being the rate-limiting enzyme. Hair melanins are formed in cytoplasmic organelles called melanosomes. The melanosomes travel out to the tips of the melanocyte's dendrites where they are transferred to the hair follicle keratinocytes of the hair cortex and medulla. Each hair cycle can produce a long pigmented terminal hair because the follicle is able to replace these melanocytes from a reserve found in the bulge region of the ORS [39]. As individuals age, the melanin content of the hair follicle decreases, causing graying and eventual whitening of the hair. Although poorly understood, numerous mechanisms have been suggested for this loss of hair follicle pigment, including pigmentary machinery malfunction or loss, melanocyte apoptosis, anagen defects, the loss of melanocyte stem cells or their failure to differentiate, and melanocyte migration defects [40].

Hair graying, sometimes referred to as canities, is one of the most prominent signs of human aging. A recent worldwide survey showed that 74% of people between the ages of 45 and 65 have gray hair, and that it occurs earliest in people of Caucasian descent, followed by lesser occurrence in Asians and Africans [41]. The age of graying onset is genetically controlled and inheritable. Hair is considered to gray prematurely only if it occurs before the age of 20 years in Caucasians, before 25 years in Asians, and before 30 years in Africans [42]. As hair color is socially important, premature graying imposes a psychosocial distress and is often perceived as a sign of stress, old age, ill health, and bodily decline [42, 43].

Both the hair and scalp are constantly exposed to various environmental stressors. These include UV irradiation as well as oxidative and chemical stressors. The effect of external stressors on the hair fiber is quite well documented. In particular, repeated sun exposure impairs the structure of the hair shaft keratin fiber, while UV radiations induce hair protein loss and color changes [44]. Recent *in vitro* and *ex vivo* studies have investigated the damage caused by UV radiation and oxidative stress on the hair follicle [45, 46]. Upon exposure to repetitive UVB irradiation isolated hair follicles in culture demonstrated reduced hair shaft elongation and premature entry into the catagen phase. Moreover, oxidative DNA damage was observed in hair follicle submitted to low UVB doses [45]. Gondran *et al.* examined the effects of UV radiation and oxidative stress generated by H_2O_2 on human scalp skin grafts containing hair follicles [46, 47]. *Oxidative stress impaired hair follicle structure as indicated by increased number of vacuoles and edema mainly observed in the outer root*

sheath. Emerging evidence shows that reactive oxygen species (ROS) accumulate in human gray/white scalp follicles up to millimolar concentrations. The presence of ROS is believed to cause oxidative damage (free radical-induced aging) to the hair follicle melanocytes [48, 49]. In addition catalase (the enzyme involved in cell response to oxidative stress), expression is reduced in unpigmented and older follicles [48, 50, 51]. Altogether, the data strongly suggest that the hair follicle itself is a direct target of oxidative stress and underline the interest of applying a specifically developed cosmetic follicle ingredient to protect the hair follicle from endogenous or environmental stressful processes [46, 47].

CONCLUSION

Hair care formulations have traditionally relied on ingredients that treat the hair fiber to improve appearance. However, vibrant and healthy-looking hair starts at the roots and, therefore, cosmetic biofunctionals that target the hair follicle provide product manufacturers with new innovative ways to bring back beauty to the hair.

GLOSSARY

Alopecia: Abnormal hair loss.

Androgenetic alopecia: Loss of hair caused by miniaturization of genetically predisposed follicles

Anagen: Growing stage of the hair follicle cycle.

Bulb: Lowermost portion of the anagen follicle containing rapidly proliferating cells that generate the hair fiber

Bulge: Site of stem cells within the follicle outer root sheath, located at the insertion site of the arrector pili muscle just below the sebaceous gland.

Catagen: Regression stage of the hair follicle cycle.

Club hair: Fully keratinized, dead hair formed during catagen.

Dermal papilla: Signaling control center of the hair follicle consisting of dermal papilla cells.

Exogen: Stage of the hair follicle cycle when hair is shed from the follicle.

Hair shaft: The hair *per se*, composed of trichocytes, which are terminally differentiated hair follicle keratinocytes. It is composed of the medulla and the cortex.

Infundibulum: Most proximal part of the hair follicle relative to the epidermis, extending from the sebaceous duct to the epidermal surface.

Inner root sheath: Surrounds and protects the growing hair.

Isthmus: Permanent middle section of hair follicle extending from the sebaceous duct to the point of arrector pili insertion

Kenogen: Stage of the hair follicle characterized by empty hair follicles after the hair fiber is shed before a new anagen hair emerges.

Outer root sheath: The outermost layer of the hair follicle. Merges

proximally with the basal layer of the epidermis and distally with the hair bulb.

Telogen: Resting stage of the hair follicle cycle.

Terminal hair: Large, usually pigmented hairs (e.g., those found on the scalp).

Vellus hair: Very short, nonpigmented hairs (e.g., those found diffusely over nonbeard area of the face and bald scalp as a result of miniaturization of terminal hairs).

HAIR AGING: FUNDAMENTALS, PROTECTION AND REPAIR

ABSTRACT

Aging skin is a concept easily grasped; aging hair is not. However, changes in hair with aging are consumer perceivable and measurable. This chapter describes the structure of hair, fundamentals of aging hair, signs of aging hair, and causes of the visible signs of aging hair. Further, it also covers remedies for protection of hair fibers, the scalp from which it grows, as well as hair products and ingredients formulated to maintain and restore youthful hair. Beyond these approaches, the author has also provided a unique cosmeticological look at selected products and ingredients on the market with commentary on their performance.

While considerable attention has been paid to the many factors affecting aging skin, it is only recently that a shift in the perception that hair is “dead” has begun to accelerate. Actually, while this is true, in part, it is also true that the core of the hair fibers is alive as well as the skin from which it grows, and much has been done and needs doing to bring it to life again.

The understanding of the hair-scalp system described in this chapter provides important leads to ingredient-seekers and product formulators and presents an opportunity for a myriad of novel products that consumers long for. The chapter is also unique in that it provides thoughtful, practical recommendations for hair care and protection. This wisdom goes beyond the traditional approach of finding new ingredients or formulations to achieve the goals of beautiful hair. It is recommended that these approaches be incorporated in recommendations by

product manufacturers as important information to consumers.

3.3.3.1 INTRODUCTION

Similar to skin, with aging, the scalp and hair are subject to intrinsic or chronological aging, and extrinsic aging due to environmental factors. The changes associated with aging skin and the mechanism of skin aging has been well researched and published extensively over the past decades. According to Mintel's global product database, nearly half of the skin care products in the market are anti-aging products.

While the aging of hair has not been studied extensively like skin aging, there are numerous studies published on hair aging[1–3], and the number of anti-aging hair care products continues to increase year by year[4]. The most obvious sign of hair aging is the appearance of gray hair that correlates closely with intrinsic aging. Melanin pigment is responsible for the natural color of hair and it is produced by melanocytes in the hair follicles. With aging, melanocytes stop producing melanin pigment, resulting in gray hair. The loss of melanin has been linked to a decrease in the number of melanocytes in the hair follicle as well as a possible decrease in the activity of the enzymes involved in melanogenesis[5]. A recent publication by Wood *et al.*[6] showed for the first time high accumulation of hydrogen peroxide in human gray scalp hair shaft, thus supporting the theory

of oxidative stress in gray hair formation. These researchers also demonstrated that H_2O_2-mediated oxidation of methionine in tyrosinase enzyme limits its functionality, which leads to gradual loss of hair color.

In addition to graying of hair, with aging, your hair will become deficient in essential nutrients and the hair follicles shrink, it loses its elasticity, lipid and keratin production diminish, and many hair follicles stop producing new hairs altogether. These internal changes cause hair to become thin, dry, less manageable, brittle and less shiny, and ultimately lead to hair fall.

Externally, the hair shaft is exposed to sunlight, environmental pollutants, chemical and heat treatments, and subjected to daily grooming and mechanical aggression-in-search-of- "beauty." These environmental insults and daily aggressors alter the chemical and physical properties of the hair fiber. When hair is exposed to sunlight, severe damage occurs due to lipid, protein, and melanin oxidation. This results in loss of mechanical strength, loss of color, an increase in porosity, as well as an increase in surface roughness. Other environmental pollutants such as cigarette smoke, car exhaust fumes, and smog also impart hair damage, resulting in dull and brittle hair. These physicochemical changes in hair structure and damage caused by aging are measurable and also perceivable to the consumer.

Several methods involving microscopic techniques, differential scanning calorimetric, wet and dry combing measurements, protein loss, and assessment of tensile properties of the hair are generally used to evaluate the various physicochemical changes to hair[7]. These approaches are useful in characterizing aging changes as well as the effect of "treatments" that may improve the detrimental effects of the various stressors.

Hair loss is another significant aspect of aging that occurs gradually with a progressive thinning of hair. With aging, less protein is produced in the hair follicle that can cause hair to fall out and not to be replaced as quickly as desirable. This causes baldness, as well as thinning of hair. Unlike the long term, initial focus on the skin of women, the baldness phenomenon is also a men's "condition" and any impact of novel approaches to reduce hair loss and hair thinning represents an area of potential product growth for both men and women.

Experimental evidence supports the hypothesis that oxidative stress also plays a role in hair aging. The damaging effects of these reactive oxygen species are induced internally during normal metabolism and externally through exposure to

various oxidative stresses from the environment. The body possesses endogenous defense mechanisms, such as antioxidant enzymes (superoxide dismutase, catalase, glutathione peroxidase) and non-enzymatic antioxidative molecules (e.g., vitamin E, vitamin C, glutathione, ubiquinone), protecting it from free radicals by reducing and neutralizing them.[9] With age, the production of free radicals increases, while the endogenous defense mechanisms decrease. This imbalance leads to the progressive damage of cellular structures, presumably resulting in the aging phenotype.

Nourishment and proper grooming are very important to maintain the beauty of hair as perceived by: good hair texture, healthy growth, shine, and luster. Eating foods rich in vitamin A, B, minerals, and proteins is necessary for promoting a healthy scalp and hence healthy hair growth. Eating a diet rich in dark green vegetables, orange and yellow fruits, sprouted whole grains, cereals, meat, and soy helps maintain a healthy follicle. It is equally important to use good scalp care and hair care products to protect the hair shaft from damage due to sunlight, pollution, and other daily aggressors. For daily washes, use a shampoo that is mild, gentle, and moisturizing. Anti-aging hair care topical and ingestible products enriched with vitamins, lipids, proteins, vegetable oils, and antioxidant rejuvenate the scalp and follicle, and encourage new, more resilient growth from the root.

This chapter describes the fundamentals of aging hair, signs of aging hair, and the causes of visible signs of aging. Further, it also surveys current remedies for protection of the hair fiber, along with hair products formulated to maintain and restore youthful hair.

3.3.3.2 STRUCTURE, COMPOSITION, AND NATURAL COLOR OF HAIR

Hair is composed of two parts, the hair follicle and the hair shaft. The hair follicle is a tiny cup-shaped point located in the dermis from which the hair grows. The hair follicle consists of the hair bulb, the inner root sheath, and the hair shaft (see Figure 1).

Figure 1. Cross-Sectional Image of Hair Bulb Structure

New hair is made inside the onion-shaped hair bulb that lies within the hair follicle. The hair bulb also contains some special cells called melanocytes that produce melanin, the pigment responsible for the natural color of hair. The part of the hair seen above the scalp is called the hair shaft. It consists of three layers; cuticle, cortex, and medulla (see Figure 2).

Figure 2. Structure of Human Hair Fiber

The outermost layer called cuticle is a thin and colorless layer made of several overlapping scale-type structures. It is responsible for the visual attributes of hair such as shine and smoothness. It is also responsible for the friction effect of hair, which determines manageability (i.e., how easy it is to comb or brush hair). The cuticle layer can be damaged by daily grooming such as combing and brushing as well as by chemical treatments such as bleaching or relaxing. The middle layer of the hair shaft is called the cortex, made of keratin fibers. The strength, color, and texture of a hair fiber are provided by the cortex. The innermost layer of the hair shaft called medulla is only present in large and thick hairs.

Melanocytes are the cells responsible for the natural color of hair, which are

large star-shaped cells with branches called dendrites. They are mainly found at the bottom of the hair follicle, where they produce melanin in the form of small grains of colored pigment. Melanocytes inject these pigments into the keratinocytes of the hair shaft by lengthening their dendrites. Melanocyte produces two types of melanin: eumelanin and phaeomelanin. Eumelanin occurs in the form of a small rice-like granule having a color varying between brown and black. Melanin is formed by the oxidation of an amino acid, tyrosine by the enzyme tyrosinase. The higher the concentration of eumelanin, the darker the color of hair.

The actual appearance of hair, and its overall reflective quality, is determined primarily by the pigment type, but also by the density and distribution of the pigment granules. Phaeomelanin has a less precise shape and can be seen in the form of diffuse spots. Its color varies from yellow to red. Phaeomelanin differs from eumelanin because, in addition to tyrosine, another amino acid, rich in sulfur (cysteine), is involved in its production. There are two different types of eumelanin (brown eumelanin and black eumelanin). A small amount of brown eumelanin in the absence of other pigments apparently causes blond hair.

Although people with dark hair may still produce the yellow-orange pheomelanin, it is largely masked by the dark eumelanin pigment and cannot easily be seen. However, the red-yellow pheomelanin is believed to cause the warm, golden, or auburn tones found in some types of brown hair. The range of colors produced by melanins is limited to shades of yellow, brown, red, and black. Gray hairs contain only a few melanin granules, spread throughout the hair. White hairs contain no melanin at all: their whiteness is an optical effect, due to the way they reflect the light.

3.3.3.3 FUNDAMENTALS AND SIGNS OF AGING HAIR

When considering the phenomenon of hair aging, genetic, hormonal, and environmental factors need to be taken into account. Similar to skin, the scalp and hair are subject to intrinsic aging depending on individual genetics and hormonal factors and extrinsic aging due to environmental factors. Intrinsic aging or chronological aging results in graying of hair due to a decrease in melanin production and loss of hair due to androgenic alopecia. Extrinsic factors include ultraviolet radiation, pollution, smoking, diet, and lifestyle. All these extrinsic factors progressively degrade the hair fiber through oxidation of lipids, cleavage of disulfide bond, degradation of amino acids, and oxidation/bleaching

of melanin pigment.

The effects of age-related changes in hair density, hair diameter, hair lipids, and hair color (graying) produce changes in hair fiber properties. These changes in properties impact important consumer hair assembly properties such as ease of combing, hair body, hair coverage, frizziness, shine, manageability, and style retention. There are many visible signs of aging hair that are measurable and consumer perceivable. *The most critical aging attributes are thinning of hair, loss of color, moisture, shine, and manageability.*

Thinning of Hair

Both men and women tend to lose hair thickness and amount as they age. Baldness is not usually caused by a disease. It has been found that poor diet, stress, aging, and pollution are the most common factors that damage hairs and cause hair loss. Scientifically, health experts have found that the growth of dihydrotestosterone (DHT) hormone on the scalp is responsible for hair loss. With aging, hair loss is experienced more rapidly because the amount of DHT increases with increase in age. This hormone makes hair follicles weaker and weaker by blocking the nutrients and water to the hairs. Over time, the follicle can shrink, causing the hair to become shorter and finer and finally the hairs fall from the scalp. Figure 3 shows the picture of a normal hair follicle compared to a finer follicle and a very small hair follicle, which results in baldness.

Figure 3. Picture of a hair follicle showing shrinkage over time

According to the American Hair Loss Association, around two-thirds of U.S. men will have experienced some degree of hair loss by the age of 35, and about 85% of men will have significantly thinning hair by the age of 50. Although hair loss is typically associated with men, figures state that women make up 40% of

all hair loss sufferers in the U.S., showing that hair loss is a condition that can affect us all. Recent studies claim that 16% of women under age 50 are affected, which increases to 30–40% of women aged 70 years and over[10]. The thinning of hair in women may become rather more pronounced after menopause when there are fewer estrogen hormones to counteract the androgens. Men tend to have baldness while women have thinning of hair and preservation of the frontal area.

Hair loss treatment products are mostly designed to act as DHT blockers. In recent years, two pharmacological agents have become available to treat male pattern baldness. Neither is fully effective in all cases. Both need long-term administration or there will be recurrence. Both must be prescribed on private prescription. Minoxidil is provided in 2% and 5% solutions that are applied to the scalp twice daily. The 5% solution is for men only. One study found that the 5% solution was 45% more effective than the weaker strength after a 48-week trial and was the preferred treatment for men[11]. It may well be months before any improvement is seen and it should be discontinued if there is none after a year. A solution of 5% minoxidil in cutaneous foam is now available, which is developed for ease of use. The product instruction requires application of half a capful to the scalp twice a day but the treatment should be stopped if there is no improvement after four months.

Recently, the natural hair loss treatment, **Provillus™**, has gained significant popularity for its effective dual-step formula to treat the hairs of men and women accordingly as it offers different formulations for both. The treatment, clinically proven to regrow hair, consists of a powerful blend of natural herbs and has been approved as safe and beneficial formula by health experts and FDA. The two-step formula consists of a hair regrowth supplement and a hair regrowth spray with 5% minoxidil for men and 2% minoxidil for women, which performs dual action of preventing hair loss first and then promoting hair regrowth. The consumption of this supplement twice a day makes the hairs strong enough to fight against DHT hormone and to survive. The hair regrowth spray is a liquid to be applied over the scalp. The use of that spray twice a day promotes a thicker, stronger, and healthier hair regrowth. The product nourishes the overall health of hairs and makes them healthy, shiny, and beautiful, without any negative side effects.

Change in hair fiber diameter (fine-coarseness) is another parameter that is influenced by age. Large increases in hair fiber diameter occur during the first year in life and during the teenage years. Diameter tends to peak at about age 20 for men and in the mid-40s for women (see Figure 4). Figure 4 shows a steeper

drop for the scalp hair fiber diameter of Japanese males versus Caucasian males. A decrease in hair fiber diameter results in thin hair.

Figure 4. Hair fiber diameter of Japanese males vs. Caucasian males as a function of age (C.R Robbins pp 120)

Loss of Hair Color (Graying of Hair)

Graying of hair is a natural age-related phenomenon that varies between individuals and between different ethnicities. The biological process of hair aging has been attributed to the loss of pigment-forming melanocytes from the aging hair follicle[12]. There are many theories that explain the gradual loss of pigmentation with aging, including inactivation of tyrosinase enzyme[5] and decrease in stem cell factor[13]. Recently, a free radical theory of graying has been proposed by Arck *et al.*[14]. These authors found evidence of melanocyte apoptosis and increased oxidative stress in the pigmentary unit of graying hair follicles. Recently Wood *et al.*[6] have shown for the first time accumulation of high levels, millimolar concentration, of H_2O_2 *in vivo* in human gray/white scalp hair shaft by FT-Raman Spectroscopy. These authors further demonstrated absence of catalase and methionine sulfoxide reductase A and B enzymes. In younger people, catalase enzyme breaks down hydrogen peroxide into water and oxygen, thereby protecting melanocytes from oxidative damage by hydrogen peroxide. As we age, the decrease in the levels of catalase, combined with lower levels of methionine sulfoxide reductase enzymes, MSR A and B, which repair hydrogen peroxide damage, cause hair to turn gray. A recent study by researchers at University of Bradford demonstrated repigmentation of eyelashes and skin after reduction of epidermal H_2O_2 with topically applied narrow-band UV activated pseudo-catalase PC-KUS.[15] This further supports that accumulation of hydrogen peroxide due to decrease in catalase enzyme causes hair graying and reversal of

pigment formation is possible through introduction of pseudo-catalase type molecules through topically applied products.

Figure 5. Picture of a young hair follicle vs. gray hair follicle showing melanin particles replaced with colorless air bubbles (www.nlm.nih.gov)

Hair Dryness, Shine, and Manageability

Hair dryness also results from both intrinsic and extrinsic aging. The sebaceous gland in the hair follicle produces sebum that normally hydrates the scalp and moisturizes the hair by surrounding it with a protecting microfilm. A deficiency or lack of sebum makes the scalp more fragile, resulting in irritation and itchiness. The loss of sebum also results in loss of hair elasticity and the hair becomes dry, dull, and prone to breakage. The intrinsic production of sebum from sebaceous glands in the follicle decreases with age, particularly in females as shown in Figure 6 below.

Figure 6. Variation of sebum production on foreheads with age. Data are from C.R. Robbins, *Chemical and Physical Behavior of Human Hair, 4th edition, p. 79*

Additionally, extrinsic parameters such as frequent washing of hair, use of alcohol-containing hair products, chemical treatments, exposure to sunlight, and frequent blow-drying also cause hair dryness. Each healthy hair strand has an outer protective layer (cuticle), which is composed of fatty acids, ceramides, and cholesterol. Together, these account for 0.7–1.3% of the total chemical content of hair. Integral hair lipids are located in the cell membrane complex (CMC) of hair cuticles, and are important in the maintenance of hair integrity due to hydrophobicity, moisturization, and stiffness.

Exposure to sunlight results in degradation of cuticle lipids by oxidative damage, and exposure to alcoholic cosmetic products solubilizes lipids and removes them from hair surface. Blow-drying and frequent washing with harsh surfactants also removes cuticle lipids. The appearance of your hair, and its reflective quality, depends heavily on the condition of the cuticle. Light reflection from a smooth and intact cuticle gives shine and glossiness, resulting in youthful appearance. Loss of cuticle also makes combing and brushing difficult. A flat and smooth cuticle structure reflects light, and it is important to keep healthy and shiny hair. It is reported that replacing the essential hair lipid, **18 MEA**, results in healthier-looking and -feeling hair through restoration of the hydrophobicity of hair fiber. Further, lipid replenishment protects the hair from further damage[16].

Chemical treatments such as hair relaxing and permanent hair coloring chemically modify the hair keratin structure by disrupting the disulfide bond, which is responsible for the strength of hair. Curly hair has a higher degree of disulfide bond in the cortex compared to straight hair. The process of straightening or relaxing changes curly hair into straight hair using alkaline or other chemical relaxers. The chemical modification of the disulfide bond in the cortex of the hair shaft affects the physicochemical property of hair fiber. Frizzy hair, hair breakage, hair thinning, scalp irritation, scalp damage, and hair loss are some of the common consumer complaints due to the misuse or chronic use of chemical hair relaxers[17]. Permanent hair coloring also changes hair fiber properties due to oxidative damage of hair proteins and lipids due to the presence of ammonia and hydrogen peroxide. The oxidation of lipids makes the hair dry and dull and the oxidation of the disulfide linkage of the keratin protein makes the hair fiber weaker. However, recent hair color products are formulated with great care to minimize damage as much as possible. Additionally, the hair color kits provide after-color conditioners to be used right after coloring to provide conditioning, shine, and color protection. Regular use of products

formulated for colored hair provides conditioning, shine, and overall youthful appearance.

3.3.3.4 PHOTO-AGING OF HAIR

Photo-damaged hair shows dryness, an increase in fiber porosity, reduced strength and an increase in surface roughness. Long-term exposure to UV radiation causes severe chemical degradation to hair proteins and lipids. Photoaging of hair results in lipid oxidation, disulfide bond cleavage, tryptophan degradation, and cysteic acid formation. Hair exposed to sunlight is claimed to be more brittle, stiffer, and drier than before irradiation and exhibits a reduced water-absorption capacity. Hair pigments provide photochemical protection to hair proteins by absorbing and filtering the impinging radiation and subsequently dissipating this energy as heat. However, in the process of protecting the hair proteins from light, the pigments are degraded or bleached. Dark hair is more resistant to photo-degradation than light hair. This is due to the higher photostability of eumelanin compared to pheomelanin[2].

The most obvious effect of the photo-aging of human hair is hair lightening, an effect that is accelerated by moisture. The extent of this photochemical-induced color change is dependent on the nature of the hair pigment and is understood to involve an oxidative attack on the eumelanin or pheomelanin melanosomes. Black hair is more photostable than blond hair. This color of hair seems well protected against UV light, and light brown hair is obviously damaged by a wide range of natural sunlight. The protective action of melanin granules is limited to the melanin-rich cortex of black hair, which shows only a slight modification of fiber proteins under irradiation[18].

3.3.3.5 PROTECTION OF HAIR FROM AGING

a. Scalp Care

Adequate care of scalp and shaft hair is critical to protect the hair from aging and to have healthy beautiful hair. Beautiful hair comes from a healthy scalp and hence taking care of the scalp is just as important as taking care of hair shaft. Hair problems such as thinning or falling of hair, premature graying or breakage, dandruff, and flaking could be symptoms that indicate an unhealthy scalp. Scalp care should be chosen based on the nature of your scalp, whether it is normal, oily, or dry. Normal scalp has the right balance of sebaceous glands, so it is

generally not prone to problems like dandruff or excessive oil deposition. Shampooing three to four times a week with a normal shampoo and a light conditioner will be sufficient for this type of scalp. A warm oil treatment and massaging the scalp one to two times a month stimulates the oil gland and the massaging action improves blood circulation[i]. Coconut oil is great for all hair types. Avocado oil is one of the most emollient and moisturizing oils and is particularly good for really dry and frizzy hair.

If your scalp is oily, it is the most prone to dandruff and flaking. The excess oil that the sebaceous glands in the scalp produce tends to accumulate around the roots, clogging the pores. Such hair is usually limp and flat, making it almost impossible for volumizing or styling products to hold. Shampooing your hair every day with a deep cleansing shampoo is suitable for oily hair. If you suffer from dandruff, choose an anti-dandruff variety. Avoid using leave-in conditioners. A dry scalp causes constant itching and flaking, leaving the hair rough, dull and frizzy. As the oil secreted by the sebaceous glands is insufficient, apply oil externally and massage the scalp regularly to nourish the scalp. For dry hair, shampoo once or twice a week with a product that contains natural oils and moisturizing agents is sufficient. A thick cream-based conditioner and leave it on for about ten minutes before rinsing off makes hair smooth and soft. Get a warm oil treatment every week to stimulate the sebaceous glands. Massage your scalp thoroughly to stimulate oil secretion.

Unilever has recently launched Scalp and hair beauty therapy line of products formulated with Nutrium 10, an advanced moisturizing complex. A well-nourished scalp is the right foundation for strong, beautiful hair. For years women have been treating the wrong end of their hair. Clear Scalp & Hair Beauty Therapy made with Nutrium 10 nourishes the scalp, creating the right foundation for strong, beautiful hair. The regimen of shampoo and conditioner together is clinically proven to help restore scalp’s natural moisture balance to create the right foundation for strong, beautiful hair from root to tip. There are various regimens of shampoo and conditioner to address the needs of different hair types.

b. Hair Care

Most women will see their hair become frizzier and less manageable due to chemical treatments such as coloring, straightening, perms, and frequent washing with harsh shampoos that strip the hair of natural oils. Everyday caring of hair starting with the right shampoo, conditioner, and styling product could

cosmetically improve the appearance of shaft hair. Nourishment and proper grooming is very important to keep the hair texture, growth, shine, and luster in a good condition. For daily care, choose cleansing products that are gentle and moisturizing, preferably without harsh surfactants like sodium lauryl sulphate. Daily massaging of your hair with your fingertips helps proper blood circulation in the scalp. Apply heat-styling products to your hair before blow-drying and try to keep the setting on medium, not high. Use UV-protection hair products or wear a hat if your hair is brittle or color-treated. Choose a demi-permanent hair color product for covering gray; it doesn't contain ammonia and has less hydrogen peroxide. This type of product may not be an option if you have a lot of gray hair (more than 50%) and want to cover it, in which case you'll need permanent color.

3.3.3.6 ANTI-AGING HAIR CARE PRODUCTS

One of the latest trends in the global beauty industry is the proliferation of anti-aging hair products in the marketplace. Consequently, beauty product developers, ingredient suppliers, and brands large and small have been busy addressing the graying population in hopes of attracting the baby boomer marketplace[4].

Ingredients for hair care include the well-established ones such as: silicones for shine, quaternary ammonium compounds for ease of combing, thickening approaches such as proteins and high-molecular-weight polyquaternium polymers for conditioning[19] and polyvinylpyrrolidone for shaping and styling[20].

The hair shaft lacks biochemical processes, which gave the traditional concept that hair is dead and cannot be repaired and restored. As the root of the hair shaft is alive, hair treatments using anti-aging ingredients such as small-molecular-weight peptides, alpha hydroxyl acids, certain vegetable oils, amino acids, peptides, and ceramides can provide benefits to both the shaft and the hair root. In recent times, the hair care sector is being enlivened by entirely new ingredients as well as proprietary packages that combine the old standbys in novel ways. Anti-aging hair care specifically focuses on ingredients and products (applied both topically and in ingestible form) that can repair hair, providing more manageable and healthy looking hair.

Many ingredients are recently launched to address hair and scalp aging at the cellular level, improve follicle health, reduce hair loss, and offer antioxidant properties. These low-molecular-weight compounds penetrate the cuticle layers

of the hair shaft, enhancing its softness, protection, and manageability. They can also penetrate the scalp, enhance scalp microcirculation, and improve follicle health, thereby promoting healthier new hair growth. Recently, researchers at DuPont have shown that hair care products with the well-known anti-aging ingredient, glycolic acid (marketed as DuPont™ Glypure), penetrates through the hair shaft and delivers enhanced protection and manageability to hair by conditioning, moisturizing, strengthening, and preventing breakage[8]. It also moisturizes and exfoliates the scalp, resulting in less flaking to give the scalp a healthy look and feel.

Natural vegetable oils provide nourishing conditioning and shine to hair. Coconut oil, being a triglyceride of lauric acid (principal fatty acid), has a high affinity for hair proteins and, because of its low molecular weight and straight linear chain, is able to penetrate inside the hair shaft[21]. It is an excellent conditioner and helps in the regrowth of damaged hair. It also provides the essential proteins required for nourishing damaged hair and it softens the hair and conditions the scalp. Avocado and Jojoba oil are other oils for nourishing, conditioning, and shine benefits.

Amino acid-like L-Arginine is a nitric oxide precursor found to stimulate hair regrowth by stimulating the production of hair follicles and also to strengthen hair by nourishing the hair roots. Sunscreens are another category of anti-aging ingredients now found in a variety of hair care products, including shampoos, conditioners, and hairsprays. They prevent breakdown of keratin due to sun exposure and also keep hair dye from fading in ultraviolet light. Ingredients like Crodasorb™ UV-HPP from Croda and PARSOL® SLX provide multiple benefits like prevention of color fading, strengthening hair body, and enhancing gloss when delivered through hair color, or hair care products, especially leave-on sprays. The table below lists some advanced functional hair care ingredients popular in today's hair care market.

Table 1. Advanced hair care ingredients popular in current hair care products[ii]

Hair Care Ingredients	**Benefits**	**Supplier**
Crodafos™ HCE	Increases color intensity & color uptake. Provides better color wash fastness. Reduces hair damage as shown by hydrophobicity and combing studies.	Croda Inc
Incroquat™ Behenyl TMS-50	Hair conditioning agent, suitable for cationic emulsions, provides soft touch.	Croda Inc

ChromAveil ®	Protects the hair from the damaging effects of sunlight. Gives color protection benefits to dyed hair from UVA and protects the mechanical properties of the hair from UVB.	Croda Inc
Crodasorb™ UV-HPP	Polyester polyquaternized ingredient that is substantive to hair and protects against the damaging effects of UV-B radiation.	Croda Inc
Lustreplex®	Creates lustrous, healthy-looking hair from anionic systems. Provides frizz control, shine, detangling, and conditioning benefits.	Croda Inc
Dow Corning® CE-8411 Smooth Plus Emulsion	Repairs colored, gray, and heat-damaged hair by restoring moisturized feel, shine, & alignment. Protects hair from further damage and color loss.	Dow Corning
Dow Corning® 5-7113 Silicone Quat Microemulsion	Restores smoothness, shine, and Alignment. Prolongs hair color. Protects hair from breakage.	Dow Corning
HYDROVANCE®	Improves water retention and helps to strengthen and even repair damaged hair, for benefits the consumer can clearly feel and see.	Akzo Nobel
STRUCTURE® PQ-37P	Cationic acrylic homopolymer multifunctional rheology modifier that provides thickening and conditioning.	Akzo Nobel
Procapil™	Reinforces hair anchoring. Reduces hair loss.	Sederma
Glypure® glycolic acid	Glypure® penetrates the hair shaft to enhance the softness and manageability of hair.	DuPont
L-Arginine	Helps hair regrowth by stimulating the production of new hair follicles. It nourishes the hair root and strengthens hair.	Ajinomoto
PARSOL® SLX	PARSOL® SLX is a silicone-based UV-B absorber. Delivers multiple benefits including prevention of color fading, gloss enhancement, and conditioning.	**DSM**

Table 1. Shows ingredient information obtained from supplier websites

Anti-aging hair care products are designed to address the consumer needs such

as thinning, coloring, breakage, and drying, with emphasis on particular ingredients that target specific hair issues. Such hair care formulations are designed to deliver conditioning, thickening, and color protection, strengthening, and nourishing properties through deposition of essential oils, cationic polymers, proteins, and other nutrients. For gray hair, so far, there are no solutions for reversing the color. Hair colorants are used for covering gray, to impart color and shine and hence youthful appearance. Therefore, hair colorants can also be classified as anti-aging hair color products.

Pantene has launched PRO-V Expert Age Defy shampoo, conditioner, and advanced thickening treatment designed to work together for thicker hair strands. These products are claimed to be gentle enough for daily use on color-treated hair. Formulated with a triple blend complex (mixture of amino acids), the shampoo and conditioner help fight seven signs of aging hair: reduces breakage, prevents split ends, reduces frizz, controls unruly grays, minimizes lackluster color, improves a thin look, and minimizes dryness.

There are several professional hair care products formulated with advanced technologies that restore oils vitamins and other essential nutrients. Nexxus has launched its first anti-aging range of products that combats eight signs of aging hair: volume loss, breakage, roughness, less shine, dryness, brittleness, unruliness, and loss of color vibrancy. It replenishes and revitalizes for more vibrant, youthful-looking hair.

Nexxus Youth Renewal™ Rejuvenating Shampoo gently cleanses hair to help rebuild volume, vibrancy, and vitality. Nexxus Youth Renewal™ Rejuvenating Conditioner provides lightweight nourishment to help preserve volume, vibrancy, and vitality. Youth Renewal™ Rejuvenating Elixir lightweight leave-in treatment helps rebuild hair’s strength by reducing breakage while making hair look more youthful and vibrant in just seven days.

Alterna has launched CAVIAR Anti-Aging® Replenishing line of products comprising moisturizing shampoo and conditioner that transforms dry, brittle hair by sealing in a rich blend of lipids and essential ingredients to continually nourish and hydrate the hair. The shampoo is a luxurious, sulfate-free cleanser that restores moisture while protecting hair from color fade, daily stresses, and future damage. Both shampoo and conditioner are infused with Seasilk®, Age-Control Complex®, Enzymetherapy®, and Color Hold®. It not only helps maintain moisture, but also protects from daily stresses and delivers what your hair needs to become strong, healthy, and younger-looking. The anti-aging rapid repair spray helps add moisture and vibrancy to hair while combating natural,

chemical, and environmental stresses. It may be used as a thermal protectant when applied pre-styling, or as a finishing shine spray.

Keranique® has launched a hair revitalization system developed for women to strengthen, fortify, and thicken each and every hair shaft. There are three key components to the Keranique® System. Step 1 includes a revitalizing shampoo and volumizing conditioner. Step 2 has the hair regrowth treatment with clinically proven FDA approved ingredient, Minoxidil, and Step 3 is an amplifying lift spray to provide fullness, volume, and body.

CONCLUSION

Hair, like skin, undergoes aging both intrinsically due to chronological aging and extrinsically as a result of exposure to environmental factors such as sun, pollution, and daily grooming habits. The aging of hair results in a series of visual and measurable changes both in the scalp and hair shaft. The most obvious sign of hair aging is graying of hair while the consumer also perceives a series of changes such as thinning of hair, dryness, brittleness, loss of shine, and manageability. Prevention of scalp and hair aging is not completely possible, but there are ways to protect scalp and hair fiber from damage due to external aggressors and to minimize damage from daily grooming by choosing the right products. The chapter provides an overview of the cause of hair aging, the factors that contribute to hair aging, the visual and perceptional signs of aging, and finally a compilation of some hair ingredients and anti-aging products currently available in the market.

GLOSSARY

1. **Gray Hair :** Hair without melanin pigment
2. **Hair Follicle:** An organ and part of the skin below the scalp that produces hair.
3. **Hair Shaft:** The part of the hair that is seen above the skin
4. **Oxidative Stress:** An imbalance between oxidants and antioxidants in favor of the oxidants, potentially leading to damage, is termed ‘oxidative stress’
5. **Chronological Aging:** Age of a person measured in years, months, and days from the date the person was born
6. **Androgenic Alopecia: A** common form of hair loss in both men and women
7. **DHT:** Dihydrotestosterone (a derivative of the male hormone testosterone)
8. **18**-MEA: 18-methyl eicosanoic acid (essential hair lipid responsible for hair shine and hair integrity)

MECHANISMS OF CHANGES IN HAIR SHAPE

Dr. Manuel Gamez-Garcia, Ph.D.,

Research Fellow,
Ashland Specialty Ingredients

A note from Meyer R. Rosen, Editor-in-Chief

* This chapter brings to mind a phrase that I hope will stick in your memory for a long, long time. At its heart it is Manuel Gamez-Garcia's unique ability to describe:

The Science of Hair Beauty and the Beauty of Hair Science

ABSTRACT

Changes in hair shape can be categorized as permanent and temporary. They can also be classified as cosmetically desirable and undesirable or by a combination of any of these two categories. For instance, examples of hair shape changes desired permanently are those produced by perm solutions and alkaline relaxers. Examples of desirable temporary changes are those resulting from water-setting, hot irons, and styling polymers. Undesirable permanent shape changes are, on the other hand, those leading to frizzy hair, excessive tangling, and lack of manageability.

This chapter provides an exceptionally detailed look at the development of scientific distinctions based on the integration of polymer physics and chemistry with that of hair behavior and what impacts it in our endless search for beauty.

Whether the changes in hair shape are desirable or undesirable, all of them result from a process consisting of three main steps:

1) the softening of hair, which may involve the breakage of chemical or physical bonds, and/or protein rearrangements in the amorphous and crystalline phases,
2) the mechanical imposition of a new shape, and
3) the fixing or locking of the new shape by the re-formation of broken chemical or physical bonds. In shape changes that are desirable the occurrence of these three steps is induced purposely to create a new shape, whereas in those that are undesirable the three steps occur mostly during hair damage. This chapter will focus primarily on those aspects that are desirable from a cosmetic point of view. Those aspects produced by damage have been reviewed elsewhere (1).

We would point out that technology transfer from the world of polymer physics and chemistry has been of great value in the development and application of “novel” concepts and their use as seminal thinking points for cosmetic hair scientists. We encourage the reader to continue this approach, as much of this type of “new” thinking will open fascinating and productive pathways to novel hair care products.

3.3.4.1 INTRODUCTION

The key physical properties and mechanistic events related to changes in hair shape can be better understood when we recall that hair is a biopolymer that shares many of the physical and chemical features possessed by synthetic polymers. In fact, we can learn a great deal about hair's mechanical behavior by comparing its properties with those of synthetic polymers having a similar structure. For instance, synthetic semi-crystalline polymers, like hair, possess crystalline melting and amorphous phase glass transition temperatures (2–4).

Furthermore, the composition of hair's architecture is such that it can exhibit two types of physical behavior.

- **One type of behavior is related to the hydrophilic structure of the globular proteins in the amorphous phase.** The protein hydrophilic groups in this structure are capable of forming hydrogen bonds with water. This aspect of the structure makes it highly water swellable and susceptible to plasticization by moisture. It is responsible for the viscoelastic and softening effects produced in hair by water; Max Feughelman refers to this aspect as the "gel structure of the amorphous phase" (6).
- The other type of physical behavior stems from the non-gel structure of the intermediate filaments (IFPs). This structural aspect is comprised of an amorphous network of hydrophobic, and stiffer protein segments. These are covalently cross-linked by disulfide bonds, as well as an ordered arrangement of crystalline proteins regions, which are responsible for both shape stabilization and hair strength.

The entire amorphous phase acts mechanically in parallel with the crystalline phase and gives rise to the unique combination of viscoelasticity and strength typical of hair. This behavior is also found in semi-crystalline polymers and, incidentally, there is a remarkable similarity in the architecture and properties of hair, and a particular type of cross-linked semi-crystalline polymers, namely; those that have been synthesized to behave as shape memory polymers (SMP) (7). These polymers, like hair, also exhibit two and even more types of physical behaviors. These multiple types of behavior result in most cases from the various chemical groups or structures grafted onto main polymer chains introduced with the purpose of storing various temporary shapes (8–11).

As will be discussed later in this chapter, hair, with both its amorphous and crystalline structures, can also act as a shape memory polymer (SMP) and the mechanistic aspects related to changes in its shape can be better understood by using concepts from this field of polymer science. We would point out here that this cross-fertilization of ideas, or technology transfer, is an excellent approach for hair product developers to employ when seeking new ideas.

3.3.4.2 THE SHAPE MEMORY PROPERTIES OF HAIR

a. Definition of shape memory materials

In the scientific literature, C. Liu and C.B. Chun (8) define a shape memory material as follows:

"Shape-memory materials are those materials that have the ability to

‘memorize’ a macroscopic (permanent) shape, be manipulated and ‘fixed’ to a temporary and dormant shape under specific conditions of temperature and stress, and then, later, relax to the original, stress-free condition under thermal, electrical, or environmental command. This relaxation is associated with elastic deformation stored during prior manipulation” (2).

Currently, the most rapidly growing area in the field of shape memory materials are shape memory polymers (SMPs), and they can be either purely amorphous or semi-crystalline (12–14). Figure 1 shows a sequence of captions displaying a shape memory polymer changing its shape from a coiled temporary to a straight permanent shape after this event is triggered by elevating its temperature (15). Shape memory polymers can store temporary shapes and can recover their permanent shape by a suitable stimulus, either electrical, chemical, or temperature.

Figure 1) Transition of shape from temporary (spiral) to permanent (rod) of a polymer synthesized from poly-(ε-caprolactone) dimethylacrylate and butyl acrylate (15).

Various scientists working in this field have already listed the main physical requirements for a semi-crystalline polymer to display shape memory properties. According to C. Liu et al., these are as follows (8):

1) a relatively sharp glass transition and/or a high crystalline phase melting temperature that can be used to promptly fix the secondary shape at low temperatures and trigger shape recovery at high temperatures,
2) superelasticity (low loss modulus, high deformability) above the transition temperature that leads the shape recovery and avoids residual strain (permanent deformation) and,
3) complete and rapid fixing of the temporary shape by immobilizing polymeric chains without creep thereafter.

Synthetic polymers with shape memory properties consist primarily of two main features in their chain architecture. These are:

- A primary polymer network with network points, or cross-links that serve as a memory mechanism for the generation of a permanent shape, and
- A structure of secondary groups attached to the main network that serves as memory mechanism for the formation of temporary shapes (8).

These groups can be pendant functional moieties, grafted chains, polymer blocks, interpenetrating networks, or crystalline domains; they act as switches to release the temporary shape when activated by suitable external stimulus (see Figure 1) (7). Moisture, heat, light, and electric fields are examples of external stimulus that can release temporary shapes stored in SMPs with pendant groups or structures sensitive to them (see Figure 2) (8, 9).

Figure 2) Molecular mechanisms of shape memory polymers according to C. Liu *et al.* (8)

b. Hair is a biopolymer with shape memory properties.

In the scientific literature, biopolymers such as silk and collagen have also been reported to have shape memory properties, and thus, they have been classified as shape memory materials (16, 17). **Hair is a biopolymer that also behaves as a shape memory polymer**. Clear manifestations of this behavior and properties are the following:

1) hair has a permanent shape,
2) its shape can be changed either temporarily or semi-permanently, and
3) it can "remember" or reverse to its permanent shape when treated appropriately.

Beauticians and cosmetic scientists, aware of these properties, have been creating fashionable hairstyles for years that can be reversed when desired. An example of hair's ability to recover its permanent shape can be seen in Figure 3, where it is shown that a curly temporary water-setting in a woman's hair (Figure 3a) can return to its original straight shape after washing the hair (Figure 3b).

Also, Figure 4 displays a sequence of micrographs of a hair fiber recovering its permanent shape from temporary straight to its curly permanent shape.

Figure 3) Captions of hair in a woman before (a) and after (b) it recovers its straight shape from a water temporary setting (18).

Figure 4) Captions showing sequence of a single hair fiber recovering its permanent shape from a straight temporary shape to a curly shape after water immersion (18).

As in the case of synthetic polymers, the permanent and temporary shape memory sites in hair reside in its crystalline and amorphous phases. In the case of hair, these polymeric entities are of natural origin and located in the macro-fibrils of the cortical cells. These can be listed as follows:

a) a protein crystalline phase forming intermediate filaments which serves as permanent shape memory and is also capable of storing a temporary shape when its crystalline structure unfolds or when it denatures above its melting temperature Tm.
b) a disulfide bond cross-linked protein amorphous phase capable of storing temporary shapes when it becomes soft at the hair's glass transition temperature Tg, or when it undergoes disulfide bond interchange. This

structure also contributes to the stability of the crystalline phase, and

c) an extended structure of hydrophilic protein groups located at the surface of globular proteins in the amorphous phase. Its structure forms a gel, is sensitive to moisture, and is also capable of storing a temporary shape.

c. Temporary shape memory in hair

The most common temporary or secondary shapes in hair are stored by physical means. The position of storage is in the protein regions with high levels of hydrogen bonding, i.e., in the soft gel structure of the amorphous phase (6). A typical example of this mechanism is water-setting. The gel structure in hair is ubiquitous in all types of hair and plays a crucial role in most temporary shapes imposed by hair movement and daily grooming practices. It is part of the amorphous phase, and behaves like a material that exhibits variable viscosity depending on the shear rate it is exposed to (i.e., pseudoplastic with a yield stress). This type of behavior can turn hair from very soft and flexible to very hard and brittle and, in doing so, it can virtually lock-in almost any temporary shape in hair. The viscosity of the gel structure depends on the hair's moisture content and, when hard and brittle, it presents a high opposition to the imposition or recovery of any type of shape in the hair. Temporary shapes in hair can also be stored by processes involving vitrification of the disulfide cross-linked amorphous phase and rearrangements of the crystalline phase. A typical example of this is the case of setting hair with hot irons.

The ideal creation of temporary shapes in hair shouldn't involve permanent and irreversible modifications to the protein architecture of hair. This means that after creating a temporary shape, the hair's permanent shape memory should remain intact, i.e., irreversible protein denaturation in crystalline filaments or irreversible breakage of covalent bonds in main protein chains and pendant groups should not be allowed to occur. If these irreversible phenomena occur, the hair may lose part or all of its permanent shape, becoming shapeless, and the imposition of a temporary shape will thus be irrelevant. As will be seen later, when hair is heated above its melting and glass transition temperatures with hot irons, temporary shapes can be created but at the expense of producing some of these unwanted irreversible phenomena.

d. The apparent permanent shape in hair

The hair shape that we normally perceive in our natural hair in everyday life is an apparent shape that results from a number of unavoidable mechanical effects.

These unavoidable effects are primarily caused by hair's own weight and by inter-fiber interactions in the hair assembly. Both effects produce a temporary shape that is stored in the gel structure of hair and is always present in our everyday life. It is a form of quasi-permanent water-setting. Therefore, the hair shape that we have in our natural hair is not the "real" hair's native shape, but rather it is a very close representation of it.

We call this close representation an "apparent permanent shape" or temporary shape in equilibrium with the permanent shape. Other factors that contribute to the formation of the "apparent permanent shape" are hair length, relative humidity, and type of hair; i.e., it also depends on whether the hair is naturally straight, wavy, or very curly.

The "real" permanent shape of hair is only manifested when we immerse a single hair fiber in water so that the temporary shape imposed by its own weight and other interactions is released from the gel structure. For instance, experiments have shown that a high percentage of hair fibers from Caucasian origin that appear wavy in shape, regardless of their degree of waviness or curliness, turn into almost perfect circular coils when immersed in water (18)!

We probably have all observed these effects at one time or another upon seeing our own hair fibers floating in a pool of water. These effects are shown in Figure 5 where six single hair fibers from different origins are displayed as follows: (a) Oriental, (b), (c), (d) Caucasian, (e) Mulatto, and (f) of African origin. The shape of the Caucasian and Mulatto fibers was wavy/curly before equilibration in water. Observe in this Figure that the hair fibers of Caucasian, Mulatto, and African origin formed almost perfect circles after ten minutes of water immersion, except for the one of Asian origin. This means that the real permanent shape of most hair fibers that appear wavy in a hair assembly, is actually coiled and circular, and that the wavy pattern results from deformations mostly imposed by their own weight as the fibers hang from the scalp. Another important implication from these observations is that when hair emerges from the follicle, the shape of a high percentage of hair fibers of Caucasian origin is never wavy but rather circular with a predetermined radius of curvature. Thereafter, as the hair fiber grows longer it actually becomes wavy because it is deformed by both its own weight and the interaction with other hair fibers in the scalp.

Figure 5) Picture showing six single hair fibers after their shape was equilibrated in water as follows: (a) Oriental, (b), (c), and (d) Caucasian, (e) Mulatto, and (f) of African origin (18).

Figure 6) Picture showing four single hair fibers before and after they were hung vertically as follows: (a) Oriental, (b) and (c) Caucasian, and (d) of African origin (12). The shape of hair fibers depicted in (a), (b), (c), and (d) captions had been equilibrated by water immersion for ten minutes (18).

The above-mentioned effects are better visualized in Figure 6 where it can be seen that the circular shapes of two equilibrated Caucasian hair fibers (b) and (c) turn into wavy patterns (f) and (g) as the hair fibers hang. In Figure 4 it can also be observed that the circular coil of an African hair fiber (d) presents a very small tight curly pattern, and does not open its coil upon hanging. The hair fiber of Oriental origin (e) did not change its straight shape very much after being hung.

The observations made on the behavior of African hair are not new and rather confirm what is already known by cosmetologists and beauticians; namely, that hair with a very tight coil is not readily opened by its own weight when hanging from the scalp regardless of its length. The tight curly hair will be opened,

however, when we impose a force, either with the fingers or with other devices. As will be seen later in this chapter, hair with very tight curls, such as that depicted in Figure 6d, has a very small radius of curvature, and its modification requires processes that modify a larger number of memory sites in the hair.

The modifications introduced to real permanent shapes in hair by its own weight also explain well-recognized hair shape variations often observed in people's hair when the environmental humidity changes. Higher levels of moisture result in hydrogen bond breakage in the gel structure and, therefore, moisture affects the "apparent permanent shape" of hair.

If the permanent shape is very strong, the hair will recover its real permanent shape, either curly or limp. For instance, people with wavy hair know very well that when the relative humidity is high their hair may become curlier. In contrast, people that have straight or fine straight hair as the real permanent shape may experience a higher level of hair limpness or straightening at high relative humidities. Furthermore, the formation of this "apparent permanent shape" also gives rise to differences in hair shape depending on its position on the head. For the sake of simplicity in the following paragraphs the term "real permanent shape" will be used when referring to hair shapes without any imposed deformation; and the term "permanent shape" will be used to refer to hair shapes in equilibrium.

e. Permanent shape memory in hair

The real permanent shape of hair is cast in the cortical cells during its life cycle through the anagen, catagen, and telogen phases (19–20). It is predetermined genetically and permanently imprinted in the hair follicle by the process of keratinization when the proteins in the amorphous phase are cross-linked by disulfide bonds. Figure 7 shows typical examples of hair with different types of permanent shape. Whether the hair is straight, wavy, or extremely curly, its permanent memory shape essentially resides in the composition ratio of ortho-to para-cortical cells. At the microscopic level, however, the permanent shape of hair is imprinted in the two-phase architectural structure of hair which results from the crystalline keratin micro-fibrils embedded in a highly cross-linked amorphous network of proteins (see Figure 8). More specifically, it is imprinted in the primary, secondary, and tertiary protein structures of crystalline and amorphous phases, chemically and physically stabilized by disulfide and isopeptide covalent bonds and by hydrogen bonds, salt bridges, and dispersion forces. Both protein phases stabilize hair shape and also strengthen the fibers

mechanically.

Figure 7) Captions showing three types of natural permanent hair shape as follows: Oriental (left), Caucasian (center), and African (left).

Figure 8) Schematic representation showing two hair fibers with different shape. The permanent shape of hair, either curly or straight, is imprinted in the hundreds of micro-fibrils and amorphous protein networks forming the two-phase protein arrangement in the cortical cells (18).

f. Changes to the permanent shape in hair

Permanent changes in hair shape have very different requirements than those already outlined for temporary shape changes. While temporary changes do not require irreversible modifications to the hair structure, permanent changes do require this process. Irreversible modifications are needed, first, because it is necessary to erase or delete the permanent shape from the memory of hair, and second, because it is necessary to build a new permanent shape in the hair structure when faced with consumer demands and needs. The latter step usually requires irreversible modifications to the crystalline phase, the introduction of new chemical bonds, and the rearrangement of proteins in the amorphous phase. **Thus, permanent changes in hair shape require irreversible modifications to**

one or two properties of sites where the permanent memory of hair shape resides.

The irreversible changes may be in the form of chain scission, chemical modification of protein-pendant groups, and breakage of disulfide bonds. They can also involve irreversible protein denaturation, irreversible melting of crystalline regions, or a combination of all these factors (21). Thioglycolate salt solutions and very high pH alkaline creams used in permanent waving and hair relaxers, respectively, involve exactly this type of irreversible protein denaturation. The former is selective to the breakage of disulfide bonds in the protein chains and does not have a strong impact on other chemical bonds. The latter also breaks disulfide bonds but is less specific to them and, it breaks other bonds in the protein chains as well. In addition, the phenomenon also produces irreversible modifications to the crystalline regions and to the whole hair architecture itself (22).

g. Shape reversion

One factor often encountered in treatments geared to produce a permanent change in the shape of hair is that in many instances, they do not produce a real durable permanent change. As a result, there is a partial and gradual reversion to the original fiber shape. Lack of performance of active ingredients, poor formulation design, or poor hair treatment conditions are often the cause of this reversal. Consequently, in the case of permanent waving, various treatments have to be applied periodically to maintain the wavy shape (18). In the case of hair straightening with alkaline relaxers, shape reversion is difficult to correct because after the straightening process, the hair fibers are left weakened due to the high degree of broken covalent and other protein bonds produced by these treatments.

Shape reversion phenomena occurring after permanent waving or alkaline relaxer treatments are usually difficult to explain when using conventional mechanisms of disulfide bond breakage and re-formation. However, the shape reversion processes can be easily explained when it is considered that hair is a shape memory biopolymer with a permanent shape stored in its “memory.” As will be discussed later in this chapter, in order to successfully induce permanent changes in hair shape, not only do disulfide bonds have to be broken, but also other chemical and key structural components of the hair memory need to be modified. Otherwise, the induced shape will be semi-permanent and eventually the fibers will undergo shape reversion.

Understanding the shape memory properties of hair can pave the way to optimize processes and produce successful permanent changes in hair shape. Therefore, in the following paragraphs shape memory polymer concepts will be used to review changes in hair shape, and we encourage the reader to use this information as a foundation for innovative thinking in this field.

3.3.4.3 CHANGES IN HAIR SHAPE BY WATER-SETTING

a. The process

Water-setting, or the process of changing hair's shape with water, is by far, among all the temporary setting processes, the easiest to produce in hair. It only entails the use of water and a relatively low-temperature drying process. In order to understand it mechanistically using concepts from the science of SMPs, let us first review the key generic steps necessary to produce shape changes in semi-crystalline polymers (6), and then apply them to hair. Upon thoughtful comparison, polymers also require the same three key steps described above for changes in hair shape:

1) making fluid or softer at least one of the polymer phases,
2) imposing mechanically a new shape followed by stress relaxation in the soft/fluid phase, and
3) immobilizing the soft/fluid phase to lock-in the new shape. In general, temporary shape changes in SMPs also require keeping the polymer structure intact where the permanent shape memory is located (11).

Thus, when we want to impose a temporary shape on a semi-crystalline polymer, or by analogy, in hair, the first requirement is to keep the main polymer architecture intact. To be more specific, in the case of water-setting this implies that the disulfide bond cross-linked protein matrix and the protein crystalline regions should not be modified. Water-setting usually does not produce these modifications except when high temperatures, or large deformations are involved in the production of the temporary shape. High temperatures above 80°C may already start to produce disulfide bond breakage; while deformations higher than 5% already induce alpha to beta transitions in the crystalline phase which may be partially irreversible (23).

b. Physical processes taking place inside hair during water-setting

As outlined in the previous paragraph the imposition of temporary shapes, either

in polymers or in hair, requires three main steps (see Figure 9). For the water-setting of hair, step 1 consists of softening the gel structure of the amorphous phase by wetting the hair and allowing water to penetrate into the cortex. This first step will ensure that hydrogen bonds in the gel structure are broken by water. It is important to mention here that when water breaks hydrogen bonds in hair proteins, after step 1 the hair still has all of its covalent bonds intact, and therefore, the permanent shape memory is also unchanged (see Figure 10). As will be seen later, this contrasts with other processes where the hair becomes shapeless and completely loses its real permanent shape. In step 2, once the weak hydrogen bonds are broken, the hair is set into a new configuration with plastic rollers or with the fingers to create the desired new shape, which can be either that of light hair waves or tighter curls.

Figure 9) Schematic representation of three steps required to create a temporary shape by water-setting. The three-step process is essentially based on the breakage of hydrogen bonds in the gel structure of hair (step 1), imposition of temporary shape (step 2), and re-formation of hydrogen bonds to lock-in the new shape (step 3) (18).

Figure 10) Schematic representation of hydrogen bond breakage by water dipoles during water-setting. Other covalent bonds are not affected.

Finally, in step 3, the hair has to be rapidly dried to extract water molecules in order to re-form the hydrogen bonds in the gel structure. This process will cause

hardening of the hair, thereby locking-in the temporary shape and imposing it over the primary hair shape. Drying can be achieved by just exposing hair to atmospheric conditions or it can be accelerated with the aid of blow-dryers. If the drying process is too slow and the hair rollers are removed, the crystalline micro-fibrils and amorphous matrix with its combined elastic force will push for hair to recover its permanent shape and the temporary shape will be lost. Fast drying with blow-dryers will ensure that water is rapidly removed from the gel phase before the hair can elastically recover its permanent shape. In this manner the new shape will be locked-in.

c. Temporary shapes induced by long-term deformations

Another form of water-setting is the one that takes place when hair is subjected to involuntary deformations for extended periods of time at room temperature and high moisture conditions. This situation occurs, for instance, when sleeping, using hats, *etc.* In these cases the assembly of hair fibers is held in a configuration for various hours, and after freeing the hair from the confined environment a temporary change in hair shape is produced. The phenomenon is caused by stress relaxation in the gel structure of the amorphous phase.

As was previously discussed, the gel phase of the hair is plasticized when the amorphous phase contains moisture. Water from the environment is absorbed in the gel structure and breaks a limited number of hydrogen bonds at protein neighboring sites. When there are no mechanical stresses applied to hair, the broken and unbroken bonds stay in equilibrium. However, when deformations appear as a consequence of imposed deformations, i.e., during sleep, use of hats, etc., broken and unbroken bonds undergo a bond interchange process and the protein chains move to relax internal stresses. This process of internal stress relaxation in the gel structure locks-in the temporary shape that is produced during sleep (bed hair), or with the use of hats, *etc.* (see Figure 11).

Figure 11) Caption showing typical appearance of bed hair (18)

The imposition of new temporary shapes on hair, either during sleep, use of

hats, etc., or during water-setting, will immediately produce internal elastic stresses in the structures where the real permanent shape resides. This occurs primarily in the crystalline regions and in the disulfide protein matrix. These internal stresses will remain there as long as the temporary shape is in place and are needed for the hair to recover its permanent shape. Temporary shapes imposed by water-setting will maintain their secondary character as long as the two following conditions are met. First, the elasticity of the crystalline and amorphous phases does not change, and second, that the gel structure of the amorphous phase remains unchanged. The first condition was previously reviewed and it was referred to as a requirement for superelasticity of the SMPs. This condition is required to ensure that the polymer will always remember its permanent shape. The second condition was also reviewed previously and it relates to the absence of relaxation in the soft phase; it is required to lock-in the temporary shape as long as it is necessary until it is released by an external stimulus.

Shape changes induced by water-setting can, rapidly or almost instantaneously, be reversed by water-wetting. The process of liquid water absorption by hair causes rapid hydrogen bond breakage, softening, and swelling of the gel structure, thereby releasing the temporary shape and allowing the permanent shape to be quickly recovered. If the hair didn't behave like a shape memory biopolymer, it would not remember and recover its permanent shape and would stay deformed like a viscous resin. Thus, water-wetting acts as an external stimulus to quickly release the temporary shape from hair.

d. Limitations of water-setting

Unfortunately, shape changes induced by water-setting in hair are temporary and cannot be maintained as long as we would like nor can they be dormant forever. *It is known, for instance, that shape changes induced by water are slowly recovered even when no water-wetting processes are applied.* Temporary shapes stored in the gel structure are gradually lost because, as has previously been explained by Max Feughelman (6), the gel structure of phase M in hair is viscoelastic, and even at very low moisture contents it will always relax to the Elastic Modulus of the crystalline phase. Thus, all types of temporary shapes induced by water-setting eventually revert back to the permanent shape by a stress-relaxation process and this occurs even under very dry conditions. The process may take months but the shapes will reverse! The memory shape properties of the gel structure in hair are transient, and temporary shapes induced

by water-setting cannot be maintained for very long periods.

Another important aspect of water-setting is that, depending on the type of hair, there is a limit on the type of initial shape that can be imposed. This fact becomes more clearly understood when we analyze the following questions:

- How tight can we induce a curl in hair that is very straight, or how straight can we render hair that is very kinky?
- Can this induced curl be achieved just by using a water-setting process? In other words, is it possible to put very tight curls in natural straight hair just by breaking and re-forming hydrogen bonds? Or is it possible to render very kinky hair straight just by breaking and re-forming hydrogen bonds?

Obviously, the answer to the above is no. Everyone who has tried to straighten extremely curly hair just by using water-setting will fail.

This failure can be explained by the fact that the gel structure has only limited mechanical stiffness, and therefore, cannot completely counter the strong elastic recovery forces of permanent shape coming from the crystalline and disulfide cross-linked protein phases. In other words, the gel structure is a weak physical memory and cannot store large changes in hair shape. Thus, the strength and degree of hair curliness is very important in temporary shape changes induced by water-setting. The straightening of extremely curly hair may require additional physical modifications of other, stronger protein structures that store temporary shape. Likewise, this type of reasoning can be applied for the imposition of tight curls in straight hair with water-setting.

According to the ongoing discussion, there appears to be a rule that relates strength of shape change, and number of memory sites required to achieve the changes in shape. This rule *always* prevails when imposing temporary changes in hair shape. In the case of straightening curly hair, the rule is: **the tighter the curl, the more the elements in the architectural sites in hair's memory need to be modified to make it straight.** This means that for any particular type of hair, there is a limit in the degree of shape changes that can be imposed by water-setting. In fact, this is the reason for the use of harsher temporary hair-shaping techniques, other than water-setting, for the straightening of curly hair, such as the use of hot irons and other treatments. As will be seen later in the following paragraphs, the rule of changing shape has important consequences not only for the imposition of temporary shapes but also for engendering those of permanent nature.

3.3.4.4 CHANGES IN HAIR SHAPE BY HOT IRON TREATMENTS

a. Introduction

Changing the hair shape with hot irons is a very old practice. Museums of history already report drafts of hot iron designs made in the 18th century (see Figure 12). Hot irons became popular in the early 1900s for the straightening of extremely curly hair of African origin (24). Later, over the years the application gradually extended to other types of hair to create/enhance stronger curls or to create straight patterns in hair. Currently, there are two main types of hot irons, namely, those of cylindrical shape and those with flat plates (see Figure 13). The use of hot irons with flat plates has become very popular for the straightening of wavy hair. The wanted effects from those who use it nowadays range, in terms of achieving long-lasting behavior—from totally irreversible, or permanent types, to those of long duration and reversible behavior. Most hot iron treatments used today leave only a short temporary change in hair shape. As a result, cosmetic formulators are perennially looking for new hot iron technologies that can extend the persistence and long-lastingness of heat treatments.

Figure 12) Caption displaying draft describing hot irons used in 1858 (24)

Most of the progress made in the treatment of hair with hot irons has produced innovations in their design and in the use of new ingredients or formulations to aid in the hot ironing process. Innovations in hot iron design comprise, to mention a few: more efficient temperature control, new ceramic materials to improve surface smoothness, better and effective hot iron/hair contact area, use of steam, and the incorporation of infrared heating elements (25). To this end, progress in the area of ingredients and formulations has led to the development

of two types of products; namely,

1) those based on the use of polymers geared to enhance shape effects and also to reduce hair damage (26), and
2) those using ingredients that modify or introduce new bonds in hair.

The latter type of products in most cases requires the incorporation of heat to modify the permanent shape memory of hair; either by introducing new cross-links, or by changing the disulfide cross-linking structure of the proteins. Examples of these are the formaldehyde (Brazilean) and sodium bisulfite (Japanese) treatments; both will be reviewed later in another paragraph.

Figure 13) Main modern types of hot irons, flat hot iron (top), and rod hot iron (bottom)

b. The process

A typical hair-straightening process with hot irons consists of the following steps: 1) pre-wash and condition hair with the shampoo and conditioner of choice, 2) dry hair until it keeps about 80% of its moisture content, 2) divide hair into thin swatch sections and then apply the hot iron. The temperature of the hot iron, depending on the type of desired effects, is usually selected between 160 and 230°C. The hot iron is passed two or three times over the hair swatches from root to tip at a speed of approximately one inch/sec. During application the hot iron is held firmly but gently with the hand, so the resulting force of friction will allow smooth sliding over the hair surface, and also, will enhance heat transfer at the interface of hot iron/hair. Excessive force application with the hand should be avoided since this will unnecessarily increase friction at the hot iron/surface interface causing the hot iron to slow down or completely to stop. If this happens the hot iron will damage the hair swatch. If properly used, flat hot irons produce immediate straightening effects in hair (see Figure 14).

Figure 14) Changes in hair shape before (a) and after (b) treatment with a flat hot iron. The hair shape has been changed from permanent semi-curly to temporary straight.

Good contact between the hot iron and hair is always necessary for efficient heat transfer. It is important to recognize that heat transfer from the hot iron plates to the hair swatch is always poor because hair, like wool, is a poor heat conductor. Furthermore, because of hair irregularities at the cuticle sheath surface and in view of the formation of air pockets located between hair fibers in the swatch, there is always poor thermal contact between them. This condition causes uneven temperature gradients between hot iron surface and hair swatch. Measurements carried out by placing a thermocouple inside a hair swatch have shown that hair fibers placed in a row 100 micrometers below the hot iron surface always sense at all times an average of 20 to 25°C less than those at the row surface contacting the flat iron plate (27).

c. Mechanical action of hot irons

The mechanical action of hot irons on hair is different depending on whether we try to impose a curl on straight hair or whether we try to straighten curly or wavy hair. For instance, if we place a swatch of straight hair in a hot iron of cylindrical shape at 210°C, and press on the hair statically without motion, the hair will acquire a curled shape. In contrast, if we place a swatch of wavy or curled hair between the plates of a flat hot iron at 210°C and let it be there statically without motion, it will not become straight; the action of flattening alone will not lead to changes in hair shape from wavy/curly to straight. For hair to become straight it needs to be in motion so its length can be stretched at least until the curl opens and the hair becomes straight. Thus, there is a big difference in the way the hot iron acts mechanically. This difference depends on whether the change in shape is from straight to curly or from curly to straight. Very curly hair needs a relatively high friction imposed at the interface between the hot iron and the hair

surface so the iron plates can stretch and open the curl. In contrast, the process of changing straight hair to curly is not dependent on whether the hair is in motion or not.

Other factors that influence the friction process during the straightening of wavy hair with flat irons are the type of products applied to hair before hot ironing. Hair swatches to be ironed may contain polymers, surfactants, and oils on the surface prior to the ironing process. These ingredients, in particular, include polymers that have been placed there to aid in the styling process. The polymers appear to have an effect in preventing hair damage by eliminating uneven harsh temperature gradients that may create hot spots on the hair swatch (28). Polymers and oils can have, however, a negative effect on the hot ironing process as they can excessively increase or lower the interfacial friction between the iron and the hair surface (34). High levels of friction may cause the hot iron to stop or to produce lifting of cuticle cells and tear them away from the hair (see Figures 15 and 16), while very low friction may reduce the uncoiling of the curl compromising the efficiency of a hair-straightening process (27).

Fig 15) Micrograph of a single hair fiber showing cuticle cell deformation and lifting after treatment with a hot iron at 210°C. The colored sections represent lifted cuticle cells showing patterns of light interference (27).

Figure 16) Micrograph showing fragments on cuticle cells left on plate of hot iron after a hair bundle was treated with a hot iron. Cuticle cell removal was produced by excessive friction at hot iron/hair interface (27).

3.3.4.5 PHYSICAL PROCESSES TAKING PLACE INSIDE HAIR DURING HOT IRONING

a. Water evaporation

Anybody who has witnessed for the first time the application of hot irons to hair is struck by the hissing sound of water vapor or steam coming out of the hair as the hot iron is passed over the hair swatches. At the microscopic level this means that a large quantity of “free” and “bound” water molecules are being rapidly extracted from the protein sites in the amorphous phase. Water-absorbing groups such as amino, carboxyl, and other functional groups capable of forming hydrogen bonds lose their water in this process. As a result, the gel structure of the amorphous protein phase changes from a soft and highly plasticized gel to a hardened amorphous mass.

Experimental observations indicate that rapid water evaporation from hair starts to take place when the hot iron reaches temperatures slightly higher than 100°C. Moreover, if the temperature of the hot iron is maintained at 120°C for 15 seconds while it is in contact with the hair swatch, the hair will be fully dehydrated. This is not surprising since bulk water starts to evaporate rapidly at 100°C. Yet, observations made by scientists in the laboratory and by many stylists confirm that when the temperature of the hot iron is set between 100 and 120°C, it is difficult or almost impossible to efficiently impose a temporary shape on hair, either straight or curly (27).

Furthermore, work carried out in this area indicates that the shape of a wavy hair swatch does not change efficiently from wavy to straight even when the temperature of the hot iron is increased to 150°C. These experiments also indicate that it is not until the hot iron reaches temperatures between 150 and 230°C, that a noticeable and efficient change in shape from wavy to straight starts to appear in hair (27). These observations indicate that the physicochemical processes that are responsible for inducing changes in the shape of hair occur at temperatures ranging between 165 and 230°C, and when the hair is almost fully dehydrated. Incidentally, the only protein processes that take place inside hair within this temperature range are the melting of crystalline

proteins and the softening of the amorphous matrix. The relation of these two processes with shape changes in hair will be discussed below.

b. Phase changes and transitions in hair

The thermodynamic transitions taking place in hair when its temperature is increased from 25 to 240°C have been the subject of numerous studies (29–31). Most hair types have been shown to undergo two main thermodynamic transitions, namely a first-order transition associated to the denaturation and melting of its crystalline structure, and a second-order transition associated to the softening or glass transition of its amorphous protein structure. The melting of the crystalline structure in virgin hair occurs at Tm *156°C, and the softening of the amorphous disulfide cross-linked protein phase occurs at its glass transition temperature, Tg* 144°C.

The occurrence of these two transitions in most types of hair can be detected and confirmed by Differential Scanning Calorimetry. For instance, in Figure 17 can be seen a typical DSC thermogram showing the endothermic peak related to the melting of the hair crystalline phase. Thus, since the working temperature of a typical hot iron treatment ranges between 150 and 230°C, it is straightforward that both of these transitions take place in the hot iron straightening process. In fact, as will be seen later, the better efficiency in changing hair shape temporarily with hot irons is due precisely to the occurrence of these transitions, as they are the sites with temporary memory properties.

Figure 17) Caption of a typical thermogram obtained by DSC from hair (32).

c. The mechanisms of water and hot iron setting are different.

With the material presented thus far, it is not difficult to anticipate that the mechanism by which hot irons impose a temporary shape in hair is very different

from that occurring in water-setting. Setting hair with hot irons does not involve the key and crucial typical step of water-setting, namely that consisting of the breakage of a high quantity of hydrogen bonds to soften the gel structure followed by imposition of the new hair shape.

Setting hair with hot irons involves the formation of hydrogen bonds, but they do not contribute to imposing a new shape. In order to better understand the role of hydrogen bonding during hot iron treatments, let us start by analyzing the role of water on the properties of the gel structure in hair. When water molecules penetrate into the hair structure they adsorb and intercalate on protein-functional sites breaking hydrogen bonds between them. The breakage of these hydrogen bonds renders the gel structure of the amorphous phase softer (6). When the water molecules are removed by evaporation, the internal hydrogen bonds between neighboring protein chains re-form and transform the soft gel structure into a hard viscous gel mass.

Hair swatches to be treated with a hot iron are, however, not required to be wet, for they already contain small amounts of moisture in their gel structure. However, this limited amount of water only breaks a limited number of hydrogen bonds, and therefore, it produces a semi-soft gel structure. When hair tresses with such limited amounts of moisture enter into contact with a flat hot iron at high temperatures, there will be a rapid process of heat transfer into the hair cortical regions. For instance, if after heat absorption, the temperature of the amorphous protein and crystalline phases rises rapidly to levels higher than 160°C, there will be violent evaporation of this limited amount of water, thereby producing the hissing sound typical of hot iron treatments.

At temperatures higher than 160°C the hair will have lost most of its moisture, causing all broken hydrogen bonds to re-form with the consequent hardening of the gel structure. Systematic hair-straightening experiments carried out with Mulatto hair using hot iron temperatures ranging between 110°C and 130°C have shown that hair swatches already become fully dehydrated at these temperatures. Even in the face of full dehydration the process leads to very poor or almost no hair straightening. These observations clearly indicate that rapid hardening of the gel structure attained during hot iron treatments does not allow for an efficient change in hair shape by hydrogen bond re-formation. *In other words, hot iron treatments harden the gel structure of hair before the temporary shape is imposed on it* (27).

d. Hot iron setting: partial denaturation of micro-fibrils and vitrification of

the amorphous phase

According to the ongoing discussions, hydrogen bonding does not contribute much to changes in hair shape by hot irons. There are, however, two other important physical phenomena occurring in hair between 130 and 230°C capable of inducing temporary shapes. These are the partial melting or denaturation of the crystalline protein phase at Tm and the softening of the disulfide protein matrix at Tg. Incidentally, both types of phase transitions occur also in cross-linked semi-crystalline polymers with shape memory properties (SMPs) and are commonly used to impose temporary shapes (8). In Figure 18 a schematic diagram explains the mechanism of temporary shape storage by semi-crystalline SMPs. The mechanism involves three key steps:

a) heating the polymer above its crystalline melting and glass transition temperatures to soften the polymer,
b) deforming the polymer to impose the temporary shape, and then,
c) cooling down to lock-in the temporary shape.

Figure 18) Schematic depiction of three steps needed for temporary shape fixing in cross-linked semi-crystalline shape memory polymers according to C.Liu *et al.* (8). Step 1 comprises melting of crystalline regions (a), step 2 requires the imposition of deformations to create the temporary shape (b), and step 3 involves cooling of the polymer for the recrystallization to lock-in the new shape (c).

Since hair is also a cross-linked semi-crystalline polymer, it is straightforward that hot irons must store temporary shapes in the hair structure by a similar process. Namely, when the hot iron is set at temperatures above 160°C and passes over the hair, it melts/denatures the crystalline regions and softens the amorphous phase. Then, as the hair is in motion the hot iron plates open the curl by friction and impose the straight shape by mechanical pressure. Once the hair moves out of the hot plates with its straight shape, it cools down. Cooling at

room temperature induces a vitrification process of the amorphous phase and also a recrystallization process or a reorientation of crystalline regions (see Figure 19). In this process the molten or denatured crystalline regions and the softened disulfide cross-linked proteins vitrify; while the non-denatured crystalline proteins reorient to comply with the new shape. This process locks-in the new straight shape in hair. Because hot irons use vitrification of amorphous and reorientation of crystalline proteins as processes to store temporary shapes, the stability and durability of the shape is longer than that obtained with water-setting.

It should be mentioned here that the denaturation of crystalline regions at high temperatures in hair is always an irreversible process and, therefore upon cooling, recrystallization of denatured proteins does not occur. Experiments have shown, for instance, that as the temperature of the hot iron rises between 160 and 220°C, the level of irreversible protein melting/denaturation also increases (27, 33, 34). Furthermore, it has been observed that as the level of denaturation increased in this temperature range, and while the hair curl was maintained open under the hot iron, the character of hair straightening shifted from temporary to more permanent (27). These observations clearly indicate that hot irons induce temporary shape changes in hair by a softening and vitrification process of its two protein phases. The amorphous phase locks-in the new shape by a pure vitrification process, while the crystalline phase, by either a reorientation process of the non-denatured crystalline regions or by vitrification of the denatured ones. The straightened shape becomes more permanent in character when the level of denatured crystalline regions that vitrify increases.

Figure 19) Diagrammatic representation of three steps required for the creation

of a temporary shape in hair with hot irons. In step 1 the hair is heated to its Tg so the crystalline regions partially melt irreversibly and the amorphous protein matrix softens, in step 2 a straight shape is imposed on hair, and in step 3 the hair is cooled down to vitrify the amorphous protein regions to lock-in straight shape (27).

The hot iron process could also be detailed as follows: hot irons increase the temperature of hair above its Tm and Tg. This causes the disulfide amorphous protein matrix to soften and become fluid-like while the crystalline regions start to undergo a kinetic melting or denaturation process. The degree of crystalline protein melting will depend, however, on the thermal stability of the amorphous matrix (29). If provisions are taken to reduce disulfide bond scission, then, most of the shape change induced by the hot iron will be temporary and due to vitrification of the amorphous phase and to a reorientation of crystalline regions. However, if disulfide bond breakage occurs readily in the amorphous proteins, the changes in shape will be due to a vitrification of amorphous and denatured proteins and the changes in shape will take a more permanent character (27).

For demonstration purposes Figure 20 shows three hair fibers whose semi-elliptical shape underwent a softening and vitrification process with a hot iron at 220°C. Fiber (a) in Figure 20 shows a pronounced flattening effect on its semi-elliptical shape as a consequence of the softening/vitrification process during hot iron treatment, fiber (b) shows imprints of neighboring fibers, and finally, fiber (c) shows shape flattening due to a similar vitrification process. All these effects indicate that at a certain point during the hot ironing process at 220°C the hair proteins became very soft, viscous, and fluid-like and were able to change their geometrical configuration to comply with the hot iron geometry. Then, upon cooling, the proteins vitrified and reoriented into the new shape. The experiments also showed that these effects are only temporary, i.e., when the fibers are immersed in water they recover their original shape (34).

Figure 20) Micrographs of shape distortion produced by 4 cycles of hot irons at 210°C on hair fibers of Caucasian origin as follows: (a) flat shape distortion obtained on a single fiber with a 40 g compression force, (b) imprint left on fiber by neighboring fibers in a hair tress, and (c) deformation left in a fiber selected from a hair tress after treatment with hot iron (34)

Since temporary shape changes induced by hot irons involve only physical mechanisms, the conditions for their recovery also entail physical phenomena. These conditions are met when the protein chains in the vitrified amorphous phase enter into faster motion again. This could be done by increasing again the hair temperature above Tg or when the hair is wet. Thermal motion of main chains in polymers and proteins always occurs at room temperature, and their degree of motion is relative to their Tg. The higher the Tg in a polymer, the slower is the thermal motion of its main chains at room temperature (2). Thus, in theory, temporary shapes induced with hot irons will be very long lasting but unfortunately, the principle of superposition in polymers (2–4) also dictates that the Tg of a polymer can be lowered by a plasticizer, thereby increasing chain mobility.

Let us also remember that water is the main plasticizer of proteins, and it is also the main plasticizer of the gel structure in the hair amorphous phase (5). Even when water cannot penetrate and plasticize the crystalline regions, the effects of water in the amorphous phase have an impact on the orientation and arrangement of the crystalline phase. When the hydrophilic groups of the amorphous phase absorb water the amorphous phase relaxes, and this may result in a reorientation of the crystalline regions storing the temporary shape. The final result is a loss of temporary shape. Thus, even when temporary shapes induced by hot irons are of longer duration than those attained by water-setting, their shape is also lost when the hair absorbs water.

e. Heat transfer from hot iron to hair

It should be mentioned here that because of poor hair thermal conductivity, nonhomogeneity of cuticle cell surface, and packing irregularity of hair fibers, not all hair fibers in a hair swatch exposed to a hot iron surface will experience the same temperature. Those hair fibers in contact with the hot iron will certainly be expected to equilibrate rapidly to the hot iron surface temperature. However, those a few millimeters away from the surface will experience a much lower temperature. Systematic experiments using a thermocouple embedded in a hair

tress have shown that hair fibers in the middle of a 2 mm hair tress experience ~ 25°C less than those in contact with the hot iron (see Figure 21). Furthermore, additional experiments carried out with hair swatches ~ 1 mm thick and placed on a hot plate at 200°C showed that it takes time for heat to be transferred across a hair swatch into a metallic heat sink to equilibrate temperatures. Once equilibrium conditions are established, the temperature at the hair swatch surface not in contact with the hot plate is always ~ 60°C less than that in contact with the hot plate (see Figure 22).

The simple experiment described above does not represent realistic conditions of hot iron treatments because only one surface of the hair tress is exposed to high temperature. However, the experiment helps us to visualize the time delays needed for temperature to equilibrate across the hair tress. Therefore, we will expect that when a hot iron is passed at 160°C over a hair swatch only those fibers in contact will rapidly equilibrate temperatures with the hot iron; and these fibers will experience melting of crystalline regions and softening of the disulfide cross-linked matrix. Those fibers underneath may not experience this phenomena.

Furthermore, occurrences of the above-described transitions in hair are not only dependent on the position of the hair fibers relative to the hot iron surface but also dependent on the heating rate. For instance, it has been shown that the faster the rate of heating, the higher is the melting temperature of the crystalline regions (29). Since the hot iron is passed swiftly along the hair fibers we would expect, therefore, that if the hot iron temperature is set to 160°C, large numbers of hair fibers will not undergo these transitions. Thus, if we want all hair fibers in a swatch to experience the thermodynamic transitions required, two actions must be taken, namely, 1) to increase substantially the hot iron temperature above 160°C, or 2) to improve heat transfer across fibers. From the practical point of view, only the former action can be easily done and this can be accomplished just by setting the hot iron temperature to higher levels. This analysis helps explain why setting the hot iron temperature in the range of 170–210°C improves substantially the efficiency in hair straightening (27).

Figure 21) Schematic representation of hair swatch between hot iron plates. The experiments show that hair fibers in the middle section of the hair stress sense temperatures ~20–25°C lower than those at the periphery (27).

Figure 22) Graph showing variation in temperature as function of time (a) in a thermocouple placed at the top of a hair tress placed on a hot plate (b) an (c). The temperature of the hot plate was preset at 200 C and, then, at t=0 the hair and thermocouple were place on it (27).

f. Unwanted consequences of friction and rising hair temperature above Tm and Tg

Setting temporary shapes in hair with hot irons has advantages over water-setting or any other types of temporary setting. This is true, first, because hot irons introduce stronger changes in shape, and second, because the shapes last longer. In fact, an ideal hot ironing process would occur if the duration of the temporary shape could be controlled at will and the mechanism of shape storage would only involve reversible changes to the amorphous and crystalline phases. Unfortunately, it is very difficult to control water absorption by hair and also to prevent irreversible disulfide bond breakage and other forms of damage that occur in hair at high temperatures. Scientists studying heat damage in hair have reported the occurrence of protein oxidation, cuticle cell lifting/bulging,

formation of pores inside the hair (see Figures 23 and 24), degradation of tryptophan, and disulfide bond scission (35–37). *All these effects make the process of flat ironing far from ideal.*

The first cause of damage in hair treated with hot irons comes from the fact that the thermodynamic transitions responsible for storing the temporary shape in hair lead to processes that are not fully reversible. For instance, upon cooling, the softened disulfide cross-linked protein matrix does not return to its original native vitrified state; nor do the denatured crystalline regions recover their original crystalline structure (29). Extensive research carried out in various laboratories has already shown that when hair is heated above its Tm a process of partial irreversible protein denaturation takes place. Lack of full recovery of both amorphous and crystalline phases has been ascribed to various thermal damaging factors. Among these thermal damaging factors the most important one is irreversible disulfide bond breakage. This process causes covalent cross-linking points in the amorphous phase to decrease, thereby producing a different state of vitrification and a process of irreversible destabilization of the crystalline regions. Both processes contribute to a gradual loss of permanent shape and undesirable reduction in hair strength.

Figure 23) Micrograph of a hair fiber (φ ~ 76 µm) subjected to five treatments of hot ironing showing the presence of pores at a depth of 10 µm inside the cortex (a). By using digital filters in the image, the pores were separated and the remainder of the picture was transformed into a black background (b) (34).

Figure 24) Micrographs of a hair fiber (φ ~ 64 µm) showing image of surface

obtained with no shift in plane of focus (11a). Later the plane of focus (p.o.f.) was shifted in 27 and 32 µm, respectively; the white spots in the image are voids with sizes ranging between 3 and 10 µm. The hair fiber was subjected to five hot iron treatments with the hot iron at 190°C and a speed of 0.2 in/s (34).

Cosmetic scientists and formulators are continually working in this area to alleviate these damaging effects and to improve the widely used hot ironing process. Efforts geared into this direction have already resulted in the use of polymers that enhance straightening and decrease damage. Some groups have introduced the use of formaldehyde in hot iron applications. The use of this ingredient in combination with hot irons is very effective in almost permanently changing the shape of hair. However, because of its toxic properties its use has been banned in the U.S. The mode of action of this ingredient will be reviewed later.

3.3.4.6 HAIR SHAPE CHANGES INDUCED BY PERMANENT WAVING SOLUTIONS

a. The Process

The use of thioglycolate salt solutions to chemically reduce or break disulfide bonds in hair forms the basis for one of the most effective methods for permanently changing the shape of hair from straight into a more wavy and curly configuration. Essentially, the process consists of three basic steps that are similar to those already described for other forms of hair setting:

1) breakage of bonds to soften the hair, i.e., in this case the disulfide bonds,
2) imposition of a new shape, and
3) re-formation of bonds to lock-in the new permanent shape.

Breakage of disulfide bonds in hair is carried out by treating hair in a 7–9% solution of ammonium or sodium thioglycolate at a pH of ~ 9.5. Imposition of the new shape is made by winding hair swatches on plastic rollers. Finally, re-formation of the broken disulfide bonds is accomplished by applying a solution or cream containing 3% hydrogen peroxide to reoxidize broken bonds (see Figure 25).

Figure 25) Diagrammatic representation of three steps required for the creation of a permanent shape in hair by permanent waving treatments. In step 1 disulfide bonds are unzipped to erase memory in hair, in step 2 a curly shape is imposed, and in step 3 the broken disulfide bonds are re-formed to lock-in the curly shape (18).

b. Physical and chemical processes taking place inside hair during permanent waving

The role of step one described above in permanently changing the hair shape with ammonium thioglycolate is not just to soften the hair, but mainly to delete the permanent shape in the hair architecture. This process is carried out by the thiolate ion which unzips disulfide bonds in the amorphous structure of hair and produces a certain degree of destabilization in the crystalline regions. Then, once the old shape is partially removed and when the hair is somewhat shapeless, a new shape is introduced in the protein chains by mechanical deformation of plastic rollers. Finally, the new shape is stored in the amorphous protein phase by re-zipping the same bonds in a different configuration by using hydrogen peroxide. Unfortunately, the disulfide breakage and re-formation process modifies only one part of the memory where the permanent shape of hair is stored. Namely, it only modifies part of the tertiary structure of the amorphous proteins. However, it does not modify the crystalline phase nor it does modify the primary and secondary structure of the proteins in the amorphous phase. This means that after the ammonium thioglycolate treatment, there are still shape recovery internal stresses coming from these structures. These stresses will push gradually for the recovery of the original permanent shape in the hair fibers.

Changes in the hair shape memory with ammonium thioglycolate are consequently partial, and will result in a very slow shape reversion process. At the molecular level this process is driven by the recovery of protein conformations to their native state. The forces driving this phenomenon stem from the primary and secondary structures of hair proteins in the crystalline and

amorphous phases. It should be mentioned here that the phenomenon of shape reversion is common in a host of denatured proteins and enzymes and, in particular, when it is related to disulfide bonds.

In a famous experiment, C. Afinsen showed that disulfide bond breakage/re-formation in ribonuclease leads to a mixture of denatured and scrambled protein conformations with no enzymatic activity (38). He also observed that the process of protein scrambling by disulfide bond breakage/re-formation was not sufficient for the enzyme to completely lose its shape memory or ability to revert to its native shape. For instance, Afinsen found that traces of mercaptoethanol/urea in combination with the scrambled enzymes in solution were sufficient for the enzyme to reverse and recover its native shape (see Figure 26).

Figure 26) Schematic representation of C. Afinsen's experiment with ribonuclease showing that this enzyme is able to recover its shape even after its disulfide bonds were re-formed with the proteins in a scrambled configuration (38).

It would thus appear that the ability of proteins to recover their native shape is not completely lost when their disulfide bonds are arranged in a different configuration. This particular phenomenon exhibited by proteins helps to explain why the application of treatments that produce only disulfide bond breakage/re-formation in hair are not sufficient to produce irreversible changes in its protein architecture, so that they will support the desired permanent shape changes. Disulfide bond interchange, in combination with recovery stresses coming from the residual memory in the protein architecture of the amorphous and crystalline phases, will be able to drive the reversion process.

From the practical point of view, however, thioglycolate systems are

probably the best compromise that can be made between hair damage and persistence in shape changes. Ammonium thioglycolate systems have been shown to produce shape changes that are quasi-permanent and last for months. Certainly, more effective treatments could be designed, but they will probably have to include permanent changes to the primary, secondary, and tertiary protein structures of both the amorphous and crystalline phases. Such a process could be devised but will introduce irreversible damage into other regions of the hair fiber, not to mention the practical loss of recurring business and socialization phenomena that are embedded in the perennial trek to the local cosmetologist. In summary, the process of disulfide bond breakage/re-formation for storing permanent shape changes is not 100% efficient, but it is in a good position as a system because it is very selective to disulfide bonds. It is for these reasons that many scientists working in this field have rather opted for improving the system.

In fact, there is still a great deal of improvement that can be done with these systems. For instance, the disulfide bond breaking/re-formation process is usually assumed to be fully reversible, i.e., it is commonly believed that the amount of disulfide bonds that break can be completely re-formed. Scientists have found that this is not the case and that a small percentage of these bonds always remain permanently broken (39, 40). Much effort has also been dedicated to understanding the effects of temperature, thiolate ions diffusion, and reaction kinetics inside the hair (41, 46). The process of disulfide bond re-formation by means of oxidizing agents such as hydrogen peroxide and other reagents has also been the subject of numerous studies. Effect of fiber diameter on shape changes with these systems has also been the object of concern (43–46). All these studies represent efforts geared to improving the efficiency and effects of the disulfide bond breakage process.

Surprisingly, changes in the crystalline regions after permanent waving have not received much attention and only a few studies have appeared in the literature (47). These studies, however, do not seem to correlate efficiency of shape change with levels of irreversible change in crystalline regions. Certain substances such as urea in combination with ammonium thioglycolate salt solutions appear to enhance destabilization and breakage of hydrogen bonds, apparently improving the efficiency of permanent shape changes, yet their effect on hair’s crystallinity has not been reported (48).

3.3.4.7 HAIR SHAPE CHANGES BY ALKALINE RELAXERS

a. The process

The straightening of hair with alkaline cream relaxers belongs to the category of permanent changes in hair shape. It is the most damaging process of all known hair permanent reshaping cosmetic treatments. This is so because during the alkaline straightening process not only are disulfide bonds broken, but also a series of other processes occur that damage the hair architecture. Among these processes are: permanent denaturation of hair proteins, irreversible breakage of disulfide bonds, protein alkaline hydrolysis, protein loses, and excessive swelling of hair (49–51). All alkaline straightening processes are based on the chemical reactivity of the OH ions towards the groups in hair proteins that store the permanent curly shape. The pH of these creams depends on the tightness of the curl, and it ranges between 11.5 and 14.0. As a result, the concentrations of alkaline ingredients in these creams often vary between 1.5 and 3%. Strong chemical bases are used for this purpose and these include sodium hydroxide, lithium hydroxide, combinations of lithium/sodium hydroxide, and guanidine hydroxide produced *in situ* by the combination of calcium hydroxide and guanidine carbonate.

There are various classifications of cream relaxers in the market. These are known as lye, no-lye, base, no-base, and mix, no-mix, *etc.* Regardless of their classification, the key active chemical in all of them is always the OH ion. Lye relaxers are those based on sodium hydroxide; no-lye relaxers are those containing any other ingredient than sodium hydroxide. A base relaxer refers to one that needs a layer of petrolatum on the scalp prior the straightening process to protect it from irritation; the no-base relaxer does not need petrolatum separately as it is already formulated in the cream; and finally, a mix relaxer refers to one needing the mixture of two ingredients to produce the OH ions, as is the case of the guanidine carbonate/calcium hydroxide relaxer.

Other types of chemicals used in the straightening of curly hair comprise the use of sodium bisulfite and thioglycolate salts; these systems are referred to as the Japanese and Thio relaxers, respectively. The action of these two ingredients is not based on the action of the OH ions but rather on the reactivity of the sulfite and thio groups. They are more selective to the breakage of disulfide bonds, and as will be seen later, they have advantages and disadvantages over alkaline cream relaxers. A typical salon application of a relaxer consists of three main steps: relaxer cream application, neutralization, and hair conditioning. During

the application step the cream is evenly distributed over the selected hair swatches. Almost immediately after application a diffusion of OH ions is triggered from the cream into the hair cortex via the endocuticle and cell membrane complex. As the ions diffuse they start to react with the hair proteins in the amorphous and crystalline phases. Experience shows that 15 or 20 minutes is sufficient for the cream to produce desired hair-relaxing effects.

Relaxer creams in many cases are not designed to reach reaction equilibrium conditions with the proteins in hair. Usually, their OH ion concentrations, which depend on the pKb of the base, are above that required for the hair-straightening process. Consequently, if they are left for longer periods of time on the hair, the effects can be partially depilatory. Thus, as soon as the beautician considers that the hair has been properly relaxed, the cream is rinsed out with water. At this point the OH ions are still reacting with the hair internal proteins; therefore, a neutralization process must be immediately introduced to stop the OH ion/protein reactions. The neutralization process is usually carried out with a shampoo containing citric acid. During this process a strong odor is perceived coming from liberated sulfur. Also, experiments show that the neutralizing solution turns turbid, indicating extraction of protein fragments from the hair structure (52). Because of the high level of damage to the whole hair architecture, a conditioning process is immediately introduced, mainly, to lessen fiber entanglement due to friction effects.

b. Physical and chemical processes taking place inside hair during alkaline straightening

The alkaline reshaping of very curly hair also starts by deleting the hair's permanent shape from the memory located in its architectural structure. In the case of permanent waving this could be done partially by using thio or sulfite compounds to unzip all disulfide cross-linking bonds and allow reorientation of the crystalline regions. The use of these ingredients for the straightening of very tight African-type hair is usually not recommended as it leads to a gradual shape reversion. This happens because disulfide bond breakage alone is not sufficient to delete enough shape memory from the curly hair so the straight shape will resist reversion. The degree of natural curliness in African hair is very tight and strong, and therefore, making it straight requires more changes in its protein chemical structure. This is true, in particular, on sites where the curly shape is imprinted. In other words, African hair was casted from its inception at the hair follicle with a primary, secondary, and tertiary protein architecture complying

and supporting very small radius of curvature and also high degrees of fiber elliptical shape (see Figure 27). This means that at the microscopic level the proteins in the amorphous and crystalline phases in these fibers are oriented and chemically bonded to accommodate for these geometries (see also Figure 8).

Thus, in order to attain a complete straightening effect in these curls a sizable amount of shape change or shape deletion is required. If the change in shape were from very tight curly to open curly, the amount of shape deletion in the hair architecture will be less, and this type of mild shape change would not even require the formation of new bonds to lock-in the new shape. However, complete straightening of very tight curly hair requires a higher degree of structure modification; first, because the tight curly shape has to be erased and, second, because the new straight shape needs to be locked-in. It should be recognized that the complete removal of curly shape from a curly hair fiber implies the breakage of chemical bonds that stay irreversibly broken, thus weakening the overall structure of hair. Therefore, the process of introducing a new permanent shape such as in the case of straightening curly hair may require either full reversibility of bond breakage/re-formation, or the introduction of new bonds to stabilize the new shape and also to strengthen the fiber.

Figure 27) Micrographs of a single fiber of African origin showing tight coil radius of curvature and high degree of ellipticity (18)

As was previously stated, there is a rule relating shape changes and number of sites in memory for curly hair, the rule is: **the tighter the curl, the more the elements in the architectural sites of hair's memory need to be modified to make it straight.** Sizable permanent changes in hair shape always require the annealing of stresses in the internal structure of hair. Otherwise, they will produce strong internal fiber stresses that will drive a shape reversion process. Consequently, large changes in hair shape always need the modification of a higher number of memory sites to eliminate strong reversion forces. The degree of memory deletion process can be outlined in the following manner:

- Weak curls require the breakage of a few disulfide bonds.
- Medium strong curls require a larger amount of disulfide bond breakage.
- Tighter curls require, in addition, denaturation of crystalline regions.
- Very tight curls require all of the above, plus breakage of amide linkages in the proteins as well.

By the same token, the level of chemical and physical stabilization required by the new straight shape increases in the same order.

However, regardless of degree of initial hair curliness, the steps needed to straighten hair with any type of cream relaxer are all the same and almost identical to those required for other changes in hair shape:

1) the softening of hair, which may involve breakage of physical bonds, breakage of covalent bonds, and softening of the crystalline and amorphous regions,
2) imposition of a new shape, and
3) fixing or locking the new shape by re-forming broken chemical or physical bonds, and by rearranging crystalline and amorphous regions.

The role of the first step is not only to chemically soften the hair, but in doing so, also to delete the permanent shape from the hair architecture or memory. In the second step, a new shape is introduced in the shapeless hair, and in the third step, the new shape is stored and imprinted in the memory structure of hair. If we pay close attention to these steps we will immediately realize that the efficiency of changing hair shape, from curly to straight, does not depend only on how much memory is erased but also on how efficient the process of imprinting and storing the new shape is.

In the scientific literature it has already been shown that alkaline creams lead to substantial chemical and physical modifications to the hair structure (53–57). Among the main chemical reactions and physical processes are breakage of weak and strong hydrogen bonds, breakage of salt linkages, and the formation of the following products: lanthionine, cysteic acid, sulfur, and protein fragments. These reactions proceed according to the paths shown in Figures 28 and 29.

Figure 28) Diagram showing reaction of cystine and OH ions. The reaction takes place during the alkaline straightening of African hair at pHs ranging between 13.5 and 14.0, and it leads to the production of sulfur and lanthionine (32).

Figure 29) Diagram showing additional reactions of cystine and OH ions occurring in the alkaline straightening of African hair at pHs ranging between 13.5 and 14.0 (32).

Because of the high level of bond breakage, alkaline relaxers also produce

high levels of protein denaturation in both the amorphous and crystalline regions. Figure 30 shows typical denaturation enthalpy reductions of various hair fibers subjected to a combination of alkaline and permanent waving treatments. The smaller the bar size in the graph, the higher is the degree of denaturation or disarray in the crystalline regions. All treatments in these experiments showed a decrease in the enthalpy of denaturation and some of them were more pronounced than others (32). Those treated with the alkaline relaxers alone, i.e., with NaOH and No-Lye are more real representations of the irreversible denaturation process taking place in real straightening hair practices, and they show reductions that range between 30 and 50% in their denaturation enthalpies.

Figure 30) Denaturation enthalpies of hair fibers after various treatments as follows: Untreated = fiber with no treatment, PW = fiber with permanent waving treatment, No-Lye = fiber treated with No-Lye relaxer, No-Lye+ PW = fiber treated with a combination of No-Lye straightening + permanent waving, NaOH = fiber treated with a relaxer based on NaOH, and finally, NaOH+PW = fiber treated with a combination of a relaxer and permanent waving (32).

This is the reason why alkaline relaxers are very efficient in deleting the permanent shape from the hair architecture—namely, because they modify a large number of hair's physical and chemical features in the protein structures containing the permanent shape memory; *i.e.* they break disulfide bonds, strong and weak hydrogen bonds, salt linkages, and a certain amount of amide bonds. By breaking all these bonds the OH ions render the amorphous phase extremely soft; in this process the crystalline regions also become scrambled and highly plasticized as well. The hair becomes, therefore, extremely soft and shapeless. The memory deletion process obtained by these effects does not guarantee however the imposition of a new shape, nor the process of locking-in the new

shape. For this to happen, new chemical bonds have to be introduced in combination with a process of reconstitution of the hair architecture.

c. Shapeless hair and a new straight shape

As previously discussed, when the alkaline straightening process starts to delete the tight curly shape from the hair memory, the hair fibers gradually become soft and shapeless. The new straight shape is also gradually introduced during the alkaline straightening process by the rubbing of the cream into the hair. The process of new bond formation also appears to occur as the cream is deleting the old curly shape. Experiments have shown, for instance, that if the process of hair straightening is carried out while the hair maintains its coiled shape, the straightening efficiency is less than if the curl is uncoiled and extended (52). Furthermore, if the acid neutralization step is done while the hair is kept in a more straighten configuration the efficiency in straightening also increases (52). These observations indicate, thus, that a certain amount of new bonds, most certainly lanthionine (see Figure 28) (53–59), are gradually introduced while the hair is still reacting with the cream. The straightening efficiency observed during neutralization, on the other hand, is certainly due to a vitrification process of the amorphous phase, and also to a partial reconstitution of the crystalline regions as salt linkages and strong hydrogen bonds re-form upon elimination of the OH ions.

The phenomena of fiber supercontraction and denaturation observed to occur in alkaline treated hair fibers, and reported by many scientists (60–62), cannot explain the straightening process when considered alone. These phenomena are at most manifestations of disulfide and hydrogen bond breakage and also of changes in protein conformation in the crystalline regions. Like the phenomenon of excessive water swelling, they do not impose by themselves the new straight shape or cause the locking-in of the new shape in the hair architecture. Furthermore, in terms of shape changes there are substantial differences between the processes of protein denaturation, supercontraction, and hair swelling. Protein denaturation does contribute to the removal of permanent shape from the hair architecture; while supercontraction and swelling do not, they are physical phenomena associated to destabilization of the protein structure. Protein denaturation per se, however, does not impose a straight shape; nor does it lock-in a new shape.

Currently, there are three main mechanisms that have been proposed to explain the straightening of very curly hair by alkaline creams. The oldest one

centers its arguments on the formation of lanthionine as the new chemical bond that is formed during the reaction of OH ions and hair. This bond is proposed to lock-in the straight shape (59–61).

Another mechanism introduced later bases the explanation on the phenomenon of supercontraction. This mechanism essentially proposes that the high level of contraction observed to occur in hair and wool when treated with high pH solutions is responsible for the imposition of the straight shape (60).

Yet, a more recently proposed mechanism suggests that the occurrence of protein denaturation is crucial and that lanthionine and the formation of any other products are just secondary to the straightening process (62). However, when we use concepts from the field of shape memory materials, we realize that the permanent straightening of hair must include the following steps: 1) removal of protein configurations that support the curly shape, 2) imposition of straight shape, and 3) locking-in of the straight shape, either physically or by forming new bonds.

It is quite possible, thus, that the straightening of curly hair by alkaline relaxers occurs by a combination of all three of the proposed mechanisms. Namely, 1) breakage of disulfide and protein denaturation are needed to delete the curly shape from the memory of hair, 2) a certain amount of fiber supercontraction aids during the cream rubbing process to create the straight shape, and 3) lanthionine formation is needed to stabilize the new straight shape.

Finally, it is obvious that the introduction of a straight shape in curly hair needs to be cosmetically acceptable. This means that both the new straight shape and the hair fibers need to have strength so the shape can be maintained to resist external forces without further unwanted deformation or breakage. The hair with the new straight shape has to be able to resist stresses coming from the grooming of hair, i.e., from its own weight and from hair movement produced by combing or styling, either when wet or dried. Experience tells us, however, that relaxer technology still is far from achieving this objective satisfactorily. Currently, many scientists are working to bridge this gap, and it has already been shown that for certain cases, i.e., for medium curly hair, it is possible to impose a straight shape without causing much damage.

These processes involve the introduction of new strong bonds in the protein chains, bonds that are capable of overcoming internal recovery stresses from the old permanent shape. Unfortunately, most of these new technologies are based on formaldehyde. This chemical is known to cause protein cross-linking in

proteins and therefore when used in hair it introduces new cross-links in the hair structure (63). Formaldehyde is, however, a potential carcinogen and its use has been banned in cosmetic applications.

Other hair-straightening technologies involving sodium sulfite or thiogycolate salts are more specific to disulfide bonds, but by their nature they are not efficient in fully removing the very tight curly shape from the hair memory. Consequently, later on the hair undergoes total or partial reversion to its curly shape. In summary, it can be said that the alkaline straightening of curly hair by OH ions is characterized by an efficient shape memory deletion process. It introduces a new straight shape, but it falls short of forming new bonds to lock-in the new straight shape so the final hair shape and hair fibers stay strong. We would be remiss if we did not point out that one other area needing research and improvement is the undesirable occurrence of chemical burns on the skin from the highly alkaline processes described above.

3.3.4.8 HAIR SHAPE CHANGES OCCURRING DURING GROOMING PRACTICES

a. Static vs. dynamic changes in hair shape

The imposition of temporary changes in hair shape is always carried out by external means, and depending on the way hair is handled they can be classified into two types: 1) shape changes imposed while hair is under static conditions, and 2) shape changes imposed while hair is under movement. In the first category we find water-setting, permanent waving, and alkaline straightening. All these shape changes are imposed with external devices that force the hair to stay statically or quasi-statically with almost no movement while the new shape is being imposed. By contrast, in the second category, shape changes are also imposed externally, but the temporary shape is imposed while the hair fibers are in a dynamic free or forced intensive movement. Thus, the final shape attained by the fibers is an average shape, and depends on fiber motion in the assembly. These are, for instance, shape changes produced by blow-dryers, combing devices, and by drying towels. In shape changes of the first type, the interaction of fiber to fiber is not important, while in those of the second type this interaction is extremely important as inter-fiber motion in the assembly determines the final average shape. In the following paragraphs we will focus our attention on the latter types of shape change.

b. Friction vs. bending forces in dynamic changes in hair shape

Movement of hair fibers in hair assemblies always occurs by currents of air, head motion, grooming devices, and even when wet hair is allowed to air dry. Because of hair flexibility, length, and motion intensity, the hair fibers bend, flex, and rotate inside the hair assembly. This flexion and rotation imposes instantaneous transient deformations on the fibers and ultimately leads to the formation of transient temporary shapes in the hair assembly. The transient deformations are, however, immediately countered by internal stresses coming from the permanent shape of hair. The hair assembly will stay deformed in a transient state or it will recover its shape depending on whether inter-fiber slippage occurs between fibers.

Ultimately, the degree of fiber inter-slippage will depend on the balance between single fiber bending and its frictional forces. For instance, slippage among fibers can be prevented if the inter-fiber frictional forces are larger than the bending forces. Under these conditions the hair fibers will behave as semi-solid ropes and the contact points between fibers will serve as strong welding joints that restrict inter-fiber movement. This condition occurs for low bending curvatures and high surface frictional forces, or when styling polymers are used. Polymer spot welding and high friction sites restrict fibers form moving and prevent the fibers from slippage when the hair assembly is being deformed.

Conversely, if a high degree of slippage occurs between hair fibers, then, the low surface frictional forces will not restrict inter-fiber movement. Consequently, slippage among fibers will occur and the permanent shape of both single fibers and hair assembly will be rapidly recovered while in motion. This occurs at sufficiently large bending curvatures or when there are relatively low frictional forces at the hair surfaces. These conditions correspond to the case when silicones or efficient conditioners are applied to the hair surface. The final average shape attained by an assembly is dependent on the balance between fiber slippage and friction forces. Figure 31 displays two hair tresses (a) and (b) washed with different shampoos, and showing the effects of these two conditions. Both hair tresses were cut from the same hair batch and were allowed to air dry at room temperature conditions after shampooing. Hair tress (a) was washed with a simple cleansing shampoo, while hair tress (b) was washed with a “2 in 1” conditioning shampoo containing silicone. In Figure 31 it can be seen that hair tress (b) dries with its fibers in a wavy fashion or with a shape that resembles its permanent shape, while hair tress (a) dries into a straight lump. The reason for this is that during fiber movement and drying, fiber inter-slippage in

hair tress (b) was dominant and the final hair shape was driven by natural recovery forces.

Figure 31) Effect of silicone on the temporary shape of hair after drying. Hair tress (a) was washed with a cleansing shampoo while hair tress (b) was washed with a shampoo containing silicone (64).

Thus, the effect of fiber-to-fiber interaction via surface effects has a strong influence on the acquisition of a temporary shape when the hair is in motion.

Fiber-to-fiber interaction has, therefore, a strong impact on the final shape of the hair assembly. This means that if water-setting is taking place during hair movement, the final shape of the hair assembly will be determined by the interplay between hair inter-fiber friction forces, hair drying rates, hydrogen bond formation in gel-structure, and ability of hair to recover its permanent shape. The role that these processes play in setting dynamic temporary shapes is so important that in the following sections of this chapter their interplay will be analyzed in relation to various grooming practices.

3.3.4.9 HAIR VOLUME AND CHANGES IN HAIR SHAPE

a. Definition of volume

Hair volume can be defined as the effect obtained when a bundle of hair fibers, aligned in synchrony, occupy as a whole or individually a physical space larger than their real nominal volume. Volume in hair is more about the space occupied by the hair bundle than about hair mass or fiber density. The larger the space between fibers or the larger the total volume occupied by the hair bundle, the

more volume is perceived (see Figure 32). The definition of volume also includes the ability of the hair fibers to maintain their separate space and shape in synchrony when the assembly of hair fibers is in motion. It should also be perceived when the hair bundle is at rest. These conditions imply that temporary hair shape changes, producing volume should have the strength and elasticity to recover rapidly and in synchrony with shape distortions created during movement. As will be seen later, if this does not happen, the undesirable cosmetic effect will be that of frizzy hair.

Figure 32) Caption of hair assemblies showing hair volume. The assembly of hair occupies a larger space than it would if each single fiber were shaped straight. Observe also that hair fibers are aligned in synchrony with a particular bundle.

Temporary shape changes in hair that create volume effects can be introduced dynamically while the hair assembly is in movement or also statically. The former is the focus of this paragraph, since the latter belongs to the types of static shape changes already described in previous paragraphs. There are two ways of creating volume by a dynamic process of hair in motion:

1) by imposing a wavy or curved shape in a collective assembly of hair fibers in a synchronized manner while the fibers are in motion. This process usually involves rapid water-setting; and/or
2) by increasing the distance between individual hair fibers, either by creating inter-fiber friction or by using styling polymer films to produce light wavy shapes on smaller hair bundles.

b. Main challenges in creating volume

The creation of hair volume in hair assemblies by any of the procedures described previously always entails hydrogen bond formation, even when polymers or styling resins are used. This means that for all practical purposes, the process of dynamic volume creation has many similarities to the process of

water-setting. In water-setting the temporary shape is created statically with plastic rollers, while in the production of dynamic volume the temporary shape is created usually when the hair fibers are in movement. The reason for this is that temporary shapes with volumizing or styling characteristics are commonly created in hair by people after taking a shower, and they are rapidly and conveniently created when the hair is wet and being dried. Therefore, volumizing temporary shapes created by motion are better stored in the hair gel structure of the amorphous phase while the hair is dried. In the following paragraphs of this section, attention will mainly be given to the process of creating hair volume without the use of resins or styling polymers, while the use of styling polymers will be reviewed in a later section.

The main challenge in creating temporary shapes that will result in an increase in hair volume is to coordinate the process of hydrogen bond formation with hair movement in order that an average temporary shape can be captured. Implicit in achieving this is the creation of a temporary shape whose instantaneous strength will be able to resist later shape-recovery forces arising from the permanent shape. While daunting, we note that beauticians have been producing volume in hair just by manipulating hair in motion as it dries from its wet state. As was previously discussed, temporary shapes created by hair fiber assemblies in motion are determined by the interplay between hair inter-fiber friction forces, hair drying rates, hydrogen bond formation in gel-structure, and ability of hair to recover its permanent shape.

In order to better understand the role of hydrogen bond formation and hair movement, let us imagine an ideal and imaginary case of hair volume creation, where the volumizing shapes introduced during hair movement are ideal and will be frozen and stored instantaneously by an extremely rapid process of hydrogen bond formation.

In this ideal process, hydrogen bond formation would be so fast and intense that the instantaneous hair shape acquired during movement would be fixed on hair like a photographic process that freezes a hair shape image while it is in motion. This ideal process would produce a very strong and temporary, rigid pattern of hair volume, somewhat similar to that obtained with the use of styling gels. Such a temporary shape would also resist very well the internal recovery stresses from the permanent shape. Unfortunately, this ideal process does not exist. First, because the rate of hydrogen bond formation by evaporation is slower than the instantaneous shape movement and second, because the instantaneous formation of hair shape during movement depends on the balance

between inter-fiber surface friction and shape-recovery forces. Third, and finally, such an ideal process would create a very stiff and static hair pattern that for all practical purposes contradicts one of the main characteristics of hair volume, namely, that of a synchronized hair movement as well. In layman's terms, it is a beautiful thing to watch a woman with long flowing hair shake her head and all of the long tresses move together from side to side. We state this here to bring the reader back, temporarily, to why we have spent such a significant amount of time and scientific research: in the end, all of this technical understanding is intended to bring beauty to hair!

Let's analyze then, a more realistic case; a good example might be that of a head hair assembly with straight shape fibers that are six inches long and belong to a hypothetical subject. After the hair has been shampooed, conditioned, and towel dried, the subject intends to introduce volume by blow-drying. For the sake of simplicity in the analysis, the effect of conditioning ingredients on the hair surface will be omitted. When the straight hair has been wet and towel dried, it still contains about 80% of its internal moisture and, therefore, its gel structure still is very soft because most of its hydrogen bonds are broken.

If at this point the subject introduces motion into the hair fibers, they will be bent and flexed elastically, and the whole hair assembly will be turned into an elastic scrambled irregular pattern. Then, as the subject dries the hair with a blow dryer, he/she forces the hair to move with a brush or a comb to create wavy patterns. As the hair moves and dries, simultaneously hydrogen bonds are formed in the gel structure of each hair fiber, thereby trapping a synchronized wavy temporary shape into their temporary memory. This temporary shape will increase hair volume because the wavy shape of the hair fibers will occupy more space than when the fibers were in a straight shape.

In this simplistic example only two factors affecting the formation of shape were considered. These were the effects of hair drying and hydrogen bond formation. The effects of hair inter-fiber friction, permanent shape strength, and effects of products on rates of drying were not considered. It is easy to foresee, however, that when the fibers enter in motion, the type of shape that will be produced depends on whether the surface is well lubricated or not. It will also depend on the integrity of the hair fibers. It may be that the hair assembly was previously treated with an alkaline relaxer or with other harsh chemical ingredients and thus has a low content of disulfide bonds. In such a case, the instantaneous shape that would form during movement would be very different from that which would have formed had the hair been virgin. Thus, the

instantaneous shape that forms during hair movement is also dependent on how strong the real permanent shape is. If the fiber strength and permanent shape are weak, the hair fibers will behave more like viscous fibers and will not be able to recover from instantaneous deformations created by hair movement.

Another factor that was not considered in the prior simplistic analysis is the rate of drying. If the hair contains ingredients on its surface that will retard water evaporation, or if for some other reasons water evaporation is slow, then the process of hydrogen bond re-formation to lock-in the shape in motion will be slow as well. This means that the amount of hydrogen bonds that form at each instant will be so slow that the gel structure will not have the strength to counter the internal shape-recovery forces coming from the real permanent shape. Consequently, the hair wavy pattern produced by hair movement will not be locked-in. For the temporary shape to be locked-in, the numbers of hydrogen bonds that form per second during drying have to be enough to build a hardened mass in the gel structure, so that its strength would be able to counter at any time the internal recovery forces coming from the permanent shape.

By the same token, if the ingredients favor faster drying, then the gel phase in the hair fibers will harden more rapidly, and the wavy shape in motion will be entrapped more efficiently. This analysis explains what cosmetic formulations and beauticians already know, namely, that the types of ingredients applied to hair and the rate of hair drying both have an effect on hair volume. The design of formulations that increase volume thus contain ingredients that in some way or another modify inter-fiber friction, hair drying rates, hydrogen bond formation, or permanent shape.

c. Back-combing and “static fly away”

Back-combing and “static fly away” are two different processes also often used to increase volume. They do not involve the creation of temporary hair shapes by free fiber movement and are based on a different mechanism. Back-combing essentially consists of increasing inter-fiber friction to very high levels by lifting cuticle cells (see Figure 34). The protruding cuticle cells created in this manner interlock the hair fibers at various points. The idea is to totally restrict inter-fiber slippage and movement so the bending deformations introduced during back-combing are maintained. This technique is effective in creating volume; however, it is very damaging to hair. Another way to produce volume in hair is by creating electrostatic repulsion between each hair fiber. Electrostatic repulsion in hair, also referred to as “static fly away” by the cosmetic

community, is very common in dried hair, and is due to the buildup of an excessive electric charge in hair. This charge is usually of negative polarity and can also be introduced artificially onto the hair fibers.

Figure 33) Caption showing process of back-combing ("teasing") to produce hair volume

Figure 34) Captions of hair swatches showing effects of "static fly away." There is an attraction between hair fibers of each swatch due to the relative amounts of negative charge in each one, i.e., the hair tress on the right contains a higher level of negative charge buildup (64).

The process of creating an excess of electrical charge in hair fibers is not a difficult task since hair is an electrical insulator, having very poor electrical conducting characteristics. Therefore, hair, like other electric insulators, is prone to accumulate charges on its surface. Charges are easily transferred from one electrical insulator to another when their surfaces enter into intimate contact. The direction of electric current, or flow of electrons, from one material to another has been studied and categorized for a host of insulating materials and put into a table usually referred to as the triboelectric series (see Table I). Materials at the top of the chart have an excess of negative charges trapped into their structures, and therefore tend to transfer electrons to those at the bottom of the chart. In

Table I, it can be seen that hair is below rubber, which is the material often used to make combs. When hair is combed, its surface enters into intimate contact with the rubber in the comb. Electrons are transferred from comb to hair, and thus the hair acquires a negative charge.

Table I) List of various insulating materials and their position in the triboloelectric series (65).

Since all combed hair fibers acquire the same type of charge, they repel each other, thereby creating a larger distance between them and, ultimately, increasing the hair volume of the assembly. Unfortunately, negative charge in hair does not last long since it escapes via moisture in the hair. Also, the presence of moisturizing ingredients on the hair surface reduces its ability to build up charge. Thus, when hair is highly moisturized, it cannot be charged no matter how many times it is rubbed against the comb. The deposition of certain polymers on the hair surface, however, increases charge buildup and can thus create an apparent effect of volume. The production of “static fly away” to increase volume in hair assemblies is, however, difficult to control as it depends on the rubbing intensity against the comb, i.e., excessive rubbing gives rise to excessive “static fly away.” Furthermore, “static fly away” also causes unwanted repulsion or attraction of hair assemblies in proximity, leading to frizzy hair and other unwanted effects (see Figure 34).

3.3.4.10 FRIZZ IN HAIR AND CHANGES IN SHAPE

Frizzy hair can be defined as the visual aspect of a hair assembly resulting from hair fibers that are positioned geometrically out of synchrony with the remainder of the bundle. The out-of-synchrony effect can be very small or large and can come from a few hair fibers, or almost the whole hair assembly (see Figure 35). The maximum radius of curvature of a frizzy hair fiber separating it from the

bundle can be of a few mm or larger (i.e., 1 or 2 cm). Out-of-synchrony effects appear in hair usually immediately after hair drying, and they are more pronounced in hair that has been chemically treated or in hair whose surface has been damaged. In non-frizzy hair, either curly or straight, all hair fibers are aligned in synchrony with their respective neighboring hair fibers. However, in hair with frizz, multiple hair fibers in various sections of the hair assembly separate randomly away from it, forming irregular-shaped curls or waves that are out of synchrony with the rest of the fibers in the bundle (see Figure 35).

Figure 35) Caption of frizzy hair produced by excess bleaching (left), and by repetitive hot ironing (right). Observe in both cases the large number of single hair fibers that separate out of synchrony from the bundles.

The causes of frizz arise mainly from the inability of hair fibers to recover their permanent shape during or after grooming deformations; i.e., after combing, drying, either by towel, blow-drying, or by hair movement during washing. The inability of hair to recover its permanent shape is caused by damage to the hair structure where the shape memory resides. When this happens, the hair partially or totally loses its permanent shape. Frizz can also be caused by excessive damage to the hair surface. Virgin and healthy hair has its permanent shape memory and also its surface intact. As a result, when the hair fibers are deformed, all of them respond in the same manner. In other words, when they are deformed by motion during grooming practices, they rapidly recover their shape and form an aligned bundle.

In contrast, damaged hair has its memory structures or surface damaged. This damage can be in the form of a partial destruction of disulfide networks in the amorphous phase, or in the form of irreversible denaturation of the crystalline phase. It could be said that hair fibers that present frizz do not remember their permanent shape, and therefore, are partially shapeless. Thus, when damaged hair fibers are deformed, depending on their degree of damage, they respond with shapes that are random and different. For instance, if the various damaged hair fibers undergo excessive stretching or bending during washing, combing, or

towel drying, their stretched or bent shape may stay like that or transform into a random shape. The result is that after the hair fibers are dried, their shape is out of synchrony with the remainder of the bundle.

Frizz caused by excessive damage in the cuticle cells of hair fibers is due to very high inter-fiber friction. As was previously discussed, the recovery and final shape in hair fibers during movement is determined by the interplay of the following factors: inter-fiber friction forces, hair drying rates, hydrogen bond formation in gel-structure, and ability of hair to recover its permanent shape. Those hair fibers in a bundle that present high levels of cuticle lifting will not be able to recover their permanent shape after the hair bundle is washed and dried. The reason for this is that high degrees of cuticle cell lifting causes high inter-fiber friction during fiber motion and this phenomenon results in a poor recovery of their permanent shape. Thus, in this case, the hair fibers separate from the bundle, making it appear frizzy. Another cause of frizz in hair comes from excessive static fly away. Typical examples of hair that develop frizz are excessively bleached hair, excessively dried hair, hair often treated with hot irons, and hair damaged during combing/tangling because of a lack of proper conditioning.

Frizz in hair can be reduced or alleviated by temporarily or permanently reconstructing the shape of frizzy hair. This can be done with hot irons, water-setting treatments, or even with treatments that introduce a new shape by re-forming disulfide bonds. When frizz is corrected with temporary treatments such as water-setting or hot irons, the problem is not solved, as the hair fibers will become frizzy again after washing. If it is caused by excessive surface damage, then, frizz can be reduced with treatments that smooth cuticle cells or reduce excessive inter-fiber friction. In many cases, frizz is caused by a combination of damage to the disulfide bond network, damage to the hair surface, and by the appearance of static fly away. In this case, frizz reduction can only be accomplished by a combination of various treatments.

3.3.4.11 BODY IN HAIR AND CHANGES IN HAIR SHAPE

The subjective perception of Body is one of abundant hair that is strong and healthy. It manifests itself during hair movement as a combination of hair mass and hair shape. The closest mechanical descriptor for body is the flexural rigidity of a bundle of fibers. Unlike other mechanical properties that do not take into account shape, flexural rigidity combines Bending Modulus and shape of

materials (66). This property recognizes the fact that the same mass of any material is easier or more difficult to bend depending on the way that it is shaped. For instance, it is difficult to make a sheet of paper stand up straight on a surface because it flexes and bends down easily. However, if we fold the same sheet of paper in half it will be able to stand without bending. Thus, just by changing its shape we have changed its flexural rigidity (see Figure 36).

Figure 36) Effect of shape on the flexural rigidity of a sheet of paper. The sheet of paper cannot stand up straight on a surface because it flexes and bends down easily. Observe that after folding it in half the sheet of paper is capable of remaining straight.

Figure 37) Effect of hair curliness on the flexural rigidity of hair. The bundle in the left with curly hair is able to maintain almost a straight inclination in cantilever without flexing, while the bundle in right with straight hair fibers bends more easily (64).

When we apply these concepts to hair we realize that is easier to flex a hair bundle of very fine hair when its fibers are in a straight fashion, than when a bundle of similar mass has its fibers tightly coiled (see Figure 37). Thus, shaping the fine hair fibers into a coiled configuration allows them to present higher flexural rigidity and higher body. The tighter the coil in hair fibers, the more body the hair assembly has. Furthermore, flexural rigidity in a solid body does not change with movement. However, in a hair bundle, since the hair fibers are

not tightly attached to each other, this property may change if the interplay of inter-fiber friction, hydrogen bond breakage with moisture, and drying rates are not properly set for that purpose. For instance, Figure 38 shows two hair tresses with their half-lengths standing up and their tips pointing upwards. The bundle at the left was treated with a solution of cationic particles that increased inter-fiber friction, while the bundle at the right does not contain any product on its surface. The bundle at the left is stiffer than that on the right, and it shows higher flexural rigidity and more body because its pre-formed shape was not allowed to change by the high inter-fiber friction in the bundle.

Figure 38) Effect of inter-fiber hair friction on the flexural rigidity of hair. The hair swatch at the left was surface treated with cationic particles and is able to maintain an upward position vertically without any support, while the hair swatch at the right with no treatment bends more easily (64).

Body in hair is, therefore, dependent on the following three properties:

a) hair fiber density, i.e., number of fibers per unit area,
b) intrinsic protein density,
c) inter-fiber friction, and
d) temporary shapes created in hair fibers.

Since cosmetic treatments cannot change properties (a) and (b), in order to increase body, formulators always try to maintain temporary shapes with high flexural rigidity by changing properties (c) and (d). Products that increase body are, therefore, those that can influence and create the formation of temporary

shapes with high flexural rigidity, i.e., strong wavy patterns, high inter-fiber friction, inter-fiber spot welding, high drying rates, *etc.*

3.3.4.12 HAIR SHAPE CHANGES INDUCED BY STYLING POLYMERS

Styling polymers have been used for many years to produce or enhance temporary changes in hair shape and to create fashionable styles that are difficult to achieve by water-setting. The ways to produce these styling shapes vary from beautician to beautician but they can be divided into static and dynamic processes.

Styling static processes involve the following steps:

1) applying a new shape to hair with the help of rollers or other devices while the hair still contains ~ 60–80% of its moisture,
2) applying the formulation containing the polymer,
3) letting the polymer and hair dry, and finally,
4) removing the rollers or devices.

Styling dynamic processes involve, on the other hand, the following general steps:

1) inducing movement in hair fibers with blow-dryers or fingers while the style is being created,
2) applying the polymer as the hair moves to entrap an average shape, and
3) stopping movement and polymer application and letting the hair dry.

From the mechanistic point of view, both polymer styling processes are similar to the static and dynamic water-setting described in previous sections. The only difference is that when a styling polymer is used, these materials are applied to hair via various formulations to produce temporary shapes and/or to enhance their durability. In most cases the mode of action of styling polymers in changing hair shape is external and limited to the production of seam and spot-welding junctions between hair fibers to restrict inter-fiber movement, thereby giving rigidity to the hair assembly (see Figure 39). The polymer by itself does not affect the memory shape or intrinsic structure of hair. In other words, the polymer molecules do not interact with hydrogen bonds, disulfide bonds, or the crystalline structure of hair.

Figure 39) Micrographs of a bundle of hair fibers showing formation of seam and spot welding by polymers (64)

However, formulations used as polymer vehicles may contain water or solvents that penetrate into the cortical cells and enhance or inhibit plasticization of the hair gel structure by breaking or re-forming hydrogen bonds. As will be seen later, these effects are not due to the polymer per se and have an influence on how rapidly the temporary shape is entrapped and locked-in. In the following paragraphs an analysis is made of the influence that polymers have in assisting changes in hair shape. Special attention will be given to how the polymers modify the interplay of hair inter-fiber friction, hair drying rates, hydrogen bond formation in gel-structure, and hair strength to recover its permanent shape.

The effects that formulations have on these processes will also be reviewed but to a lesser extent. Properties and composition of the various polymers used in hair styling applications will not be reviewed here, but for information purposes a list of the most common is given in Table II.

3.3.4.13 ROLE OF STYLING POLYMERS IN CHANGING HAIR SHAPE

As was previously discussed, the water-setting of hair, or the entrapment of a hair shape in movement without polymers, is very simple and controlled mainly by the interplay of hair inter-fiber friction, hair drying rates, hydrogen bond formation in gel-structure, and hair strength to recover its permanent shape. Hair shape entrapment with styling polymers adds, however, various levels of complexity to these factors not only because the polymers play externally a role on hair shape formation but also because the formulations influence the shape.

The added levels of complexity brought about by polymers and formulations are due to the following parameters:

1) rates of solvent evaporation; this will determine how rapid the polymer welding seams and spots dry and harden,
2) hair plasticization by the solvent; mainly when water is used as the solvent,
3) polymer glass transition temperature (Tg); this parameter determines how hard/brittle or soft/ductile is the spot welding, and
4) strength of adhesive joints at the hair/polymer interface. In the following paragraphs a discussion of all these factors will be made in relation to each one of the main formulations used in the styling of hair.

a. Temporary setting of hair with aerosols

In terms of entrapping a hair shape in motion, aerosol formulations are the simplest to analyze because the polymer is usually dissolved in ethanol or in combinations of this solvent with water. The reasons for the simplicity stem from the following facts: 1) the ethanol/water solution produces a very low level of hair plasticization; 2) the solvent mixtures have high rates of evaporation and, therefore, the polymer "welding spots" harden very rapidly, entrapping transient hair shapes efficiently. Thus, provided that the polymer or resin has the appropriate Tg, and that it is properly formulated and delivered from the aerosol bottle, and that the concentration of cationic charge along the polymer chain is sufficient, it will rapidly form welding seams and spots across hair fibers, restricting their motion and thereby entrapping the transient hair shape produced by movement (see Figures 40 and 41).

Figure 40) Illustration of hair in mannequin with styling polymer applied (left) and caption showing welding seams and spots (right)

Figure 41) Picture showing action of spraying a styling polymer to entrap shape of hair in motion

Aerosol formulations are also used to enhance temporary shapes produced statically, i.e., when the hair is not in motion. These types of applications do not have the complexities of entrapping an average shape produced by hair motion. The phenomena of fiber-to-fiber slippage, fiber bending, and fiber recovery from instantaneous shape deformations are absent in these cases. Temporary shapes produced under these conditions are preset by any of the methods described before for water-setting or hot irons under static conditions. In these cases the polymers are not used to entrap or capture a temporary shape from hair assemblies that are in motion, but rather are used to enhance long-lastingness of the preset temporary shape.

b. Temporary setting of hair with gels and mousses

Styling formulations like gels and mousses are based on water-soluble polymers and contain high amounts of water. Therefore, they have a double influence on shape formation while the hair is in motion. The water in these formulations diffuses into the hair and partially plasticizes the hair's amorphous phase; meanwhile the polymer/water system is able to provide a certain amount of hold to entrap a temporary shape. With polymer gel or mousse formulations the hair is put into motion with the fingers or a comb to create a temporary shape. During the application step, these formulations are administered to the hair surface with a very high shear rate. Thus, such pseudoplastic behavior results in a low enough viscosity at the high rates of shear to apply easily and effectively, but on stopping the application, the rate of shear goes to zero and the apparent viscosity rapidly increases to a very high value, thereby preventing the hair from recovering its permanent shape. Higher viscosities at zero shear rate (i.e.,

polymers that form a high-yield stress) are optimal for this approach.

Even when these formulations still contain high amounts of water, they are able to suppress internal hair recovery forces and inter-fiber slippage, providing a transient hold. Once the desired shape is attained the polymer/water system is allowed to dry, and subsequently the polymer hardens, forming “welding spots” and also seams, i.e., points of attachment across multiple hair strands, both of which restrict inter-fiber motion and give flexural rigidity to the temporary shape.

c. Mechanical properties of welding seams and spots

The complexity of hairstyle and hold ultimately depend on the mechanical properties, size, and distribution of welding seams and spots. Properties such as the glass transition temperature (Tg), susceptibility of the polymer to be plasticized by moisture, and adhesive strength at the polymer/hair interface are crucial in the final retention of temporary shape or style hold. Aerosol or sprays produce an irregular distribution of spot welding while gels and mousses yield more uniform welding patterns (see Figure 42). Furthermore, the welding patterns left by gels are, in particular, thicker and more uniform, and this explains why gel formulations, which create high-yield stresses at zero shear rate, are more suitable to create extreme styles. The distribution and amount of polymer that remains after gel application is such that the hair undergoes a transformation from a pure hair assembly to a polymer/hair composite with very different mechanical properties (68–71). The formed polymer/hair composite, depending on the polymer properties, is able to create shapes with very high flexural rigidity that can withstand high levels of relative humidity (see Figure 43).

Figure 42) Micrograph of a bundle of hair fibers showing seam welding by a gel formulation.

Figure 43) Effect of two gel formulations on the temporary hold of hair after five seconds of water immersion. The hair of the mannequin at the left was treated with a gel containing a polymer with a high Tg and low resistance to moisture, while the hair of the mannequin at the right was treated with a polymer with a high Tg but with high resistance to moisture (67).

d. Effect of polymer glass transition temperature (Tg) on styling

The glass transition temperature of a polymer is a parameter that relates to its viscoelastic behavior. Once the style is set and hair shape has been changed, the polymer welding seams and spots must withstand stress/deformations in the hair assembly arising from head movement and from the hair's own weight. The polymer also has to efficiently counter recovery stresses coming from the memory shape of hair in the amorphous and crystalline phases. These stresses will push the hair fibers for recovery of their permanent shape.

If the Tg of the polymer is too low or if its value decreases because of water plasticization, the spot welding will flow like a viscous "chewing gum" and will not be able to retain the temporary shape (see Figure 44). In contrast, if the Tg is too high the polymer will be very hard and brittle and the seams and spots will break by stress/deformations arising from hair movement. The final effect will be losses in the hairstyle and the production of "flakes" in the hair (see Figure 45).

Figure 44) Micrograph showing effects of low Tg in the seam welding of a styling polymer (65).

Figure 45) Micrograph showing flaking of a polymer due to a very high glass transition and lack of plasticizer (64).

These two effects are better visualized in Figure 46, where three typical graphs depicting changes in hair Elastic Modulus as a function of temperature are shown. The graphs correspond to three hypothetical polymers (A), (B), and (C) with different glass transition temperatures. In theses graphs, the solid line (a) represents the location of room temperature, the dotted line (b) the glass transition temperature (Tg) of the polymer, and the curved line (c) represents the variation of Elastic Modulus with temperature.

Figure 46) Graphs showing the relationship between Elastic Modulus and Temperature for three polymers with different glass transition temperatures (64).

Observe in this graph that when the glass transition temperature (Tg) of the polymer is way above room temperature, i.e., polymer A, the polymer is very stiff, and we will expect that the welding spots and seams will also be very hard and stiff. In the graph at the center with polymer B, the Tg is close to room temperature, and therefore, the seams and spots will be flexible. Finally, in the graph at the right with polymer C, the Tg is below room temperature and the seams and spots will behave extremely soft and will flow viscously. The glass transition of hair therefore has to be properly adjusted so it can provide the necessary hold without having the inconveniences of being very soft or extremely hard.

e. Adhesive strength at the polymer/hair interface

The adhesive strength at the polymer/hair interface of welding seams and spots is another important parameter in maintaining hairstyle (68, 69). The reason for this is that the polymer must be able to counter permanent shape-recovery stresses coming from the disulfide bonds and crystalline regions, and these stresses are transferred from hair into polymer via the adhesive joints. Further, the polymer needs to comply with the strong forces of hair contraction, which are produced during the de-swelling of hair. If the bonding strength of the polymer with the hair surface is weak and breaks, either because of contraction or recovery stresses, then there is no resistance to recovery, and the hairstyle will be lost soon.

In summary, styling polymers help in locking more elaborate hairstyles and temporary shapes, but they also have limitations in terms of the temporary shapes they can induce. For instance, styling polymers, no matter how high their Tg is, or how they are formulated, may not be able to straighten extremely curly

hair, or vice versa, they may not be able to produce tight curls in very straight hair. The reason for this is, again, that the polymer cannot counter the strong recovery forces coming from the permanent shape stored in the hair's memory. *Styling polymers can however contribute substantially to attaining these changes when combined with other treatments, i.e., with hot irons or other chemical treatments.*

The styling polymers used currently also have limitations in terms of complying with increasing demands of performance and with restrictions in the use of volatile organic compounds in aerosol formulations. These issues have put a lot of pressure on polymer designers and formulators to create novel ingredients that can meet performance and regulatory issues. New polymers are required to be completely soluble in water and/or at least to be partially soluble in it. This task represents a major challenge because in terms of performance, styling polymers are required to resist plasticization by moisture. Polymer synthesis scientists have responded to these challenges by creating polymers with particular pendant groups and domains that appear to provide water solubility and yet are able to transform into hydrophobic materials once they cast into dried films. The field of polymer innovations is vast and most certainly in the years to come there will be a solution to all these issues. Examples of some of these styling polymers are shown in Table II below.

Gels	**Styling Polymers – Sprays**

PVP Polyvinylphrrolidone	Octylacrylamide/Acrylates/Butylaminoethyl Methacrylate
VP/Dimethylaminoethylmethacrylate Copolymer	

Copolyme	
PVP/ DMAPA Acrylates Copolymer	VA/Crotonates/Vinyl Neodecanoate Copolymer
Hydrolyzed Wheat Protein/PVP Crosspolymer	

Acrylates Copolymer	
VP/VA Copolymer	Acrylates/Dimethicone Copolymer (Elasteesse)
Vinyl Caprolactam/VP/	Digylcol/CHDM/Isophthalates/SIP Copolymer
Dimethylaminoethylmethacrylate Copolymer	Octylacrylamide/Acrylates Copolymer

Acrylates Copolymer	Ethyl Ester of PCM/MA Copolymer
PVM/MA Copolymer	
Polyquaternium-4	
Polyquaternium-11	

Chitosan

Chitosan PCA	
Polyacrylate-3	

Mousses
Polyquaternium-4
Polyquaternium-11

Hydrophilic Polyester Polyurethane

PVP	
VP/VA Copolymer	
VP/Dimethylaminoethylmethacrylate Copolymer	
PVP/ Acrylates/Lauryl Methacrylate Copolyme	
Hydrolyzed Wheat Protein/PVP Crosspolymer	
Acrylates/ Allyl Methacylate Copolymer?	

Acrylates Copolymer	
Polyquaternium-37

EYELASHES: ANATOMY AND CONDITIONERS FOR INCREASING LENGTH AND FULLNESS/THICKNESS

By

Susan Lin, M.D.

448 N. San Mateo Drive San Mateo CA 94401 USA

ABSTRACT

This chapter describes the anatomy of eyelash hair and conditioners as well as methodology to beautify one of the most beguiling substrates related to beauty.

The history of eyelash beautification is a long one. It was first documented in Egypt with the use of a mixture of donkey feces and kohl pigmentation to paint on lashes. Lash transplant was developed about a decade ago. Commercial lash conditioners first arose in early 2000 and were composed of oil and vitamins. They only produced modest results. A flurry of prostaglandin-containing lash conditioners were developed in 2007 with one published study described below. Subsequent second-generation bioactive peptide lash conditioners and recent third-generation adipose stem-cell secreted peptide are currently on the market. In view of the vast changes in the technology, and the importance consumers place upon beautiful eyelashes as an essential part of their overall approach to looking good leading to feeling good, this chapter is worth the read.

3.3.5.1 LASH ANATOMY:

Eyelash hair is cosmetically unique and different than the rest of the hair on our body. Eyelashes are much shorter than scalp hair. Lashes are approximately 4–14 mm in length, depending on location, race, and age. Eyelash follicles extend about 2 mm deep into the dermis. Due to thinness of the eyelid, sectioning reveals a thin epidermis with the absence of hypodermis.

The upper eyelid contains approximately 300–400 eyelashes arranged in multiple rows in triangular or pyramid shape. Lower eyelashes have shorter and fewer lashes, with generally about 100–150 lashes on the lower lid.

All eyelashes are characterized by a tendency to bend from the bulb to the tip of the shaft. The degree of curvature is dependent on the asymmetric distribution of keratin 38 in the hair bulb, resulting in a curved fiber. Curvature is noted most in the African race, followed by Caucasian and least in Asians.

In contrast to scalp hair, the eyelash is free of arrector pili muscle. There are roughly 50 glands in the upper eyelids and 25 glands in the lower eyelids. Two types of glands, known as Zeis and Moll glands, surround the eyelash follicles. Zeis glands are unilobular sebaceous glands. They are found at the margin of the eyelids, producing an oily substance into the mid-portion of lash follicles. Moll glands are modified apocrine sweat glands. Meibomian glands are sebaceous glands secreting lipid to form a tear film. Melanocytes are found in very high density in three areas: the basal layer of the eyelid epidermis, the ORS, and the eyelash follicle.

3.3.5.2 LASH GROWTH CYCLE:

Length of eyelash cycle is much shorter than scalp hair, with anagen one to four months and telogen four to eight months. By comparison, scalp hair anagen phase is two to six years and the telogen phase (the transition from resting into the active growth phase) is three months. During the anagen (growth) phase, average daily growth rate is 0.12 mm with range $\pm$0.05 mm. Approximately 60–85% of eyelash follicles are in the telogen phase, in comparison to scalp which is only 15%. Thus duration of the eyelash anagen phase is strikingly shorter, with

growth rate lower than that of the scalp hair.

It has been observed that the use of lash conditioners increases the percentage of lashes in anaphase from 20 to 90% and extends the duration from four months to two years. Although the exact cellular mechanism is not well defined, it has been suggested to be through the regulation of intracellular c-AMP levels but has not yet been proven (16).

3.3.5.3 LASH CONDITIONERS:

a. History:

Synthetic prostaglandin analogues, used for the treatment of glaucoma in the form of ophthalmic drops, have been shown to result in the desired cosmetic side effect of increased eyelash length, number, and thickness (2–6). This is likely due to follicles entering the telogen phase prior to entering the anagen phase.

b. Safety Assessment:

To achieve the desired cosmetic goal of eyelash beautification by means of increasing length, number, and thickness, the novel synthetic compound dechloro ethylcloprostenolamide was developed in 2007 and its safety was assessed.

Human exposure with Human RIPT (Repeat Insult Patch Test) in 209 individuals confirmed no dermal irritation or sensitization. *In vitro* toxicity in mammalian cell was assessed and demonstrated to be non-cytotoxic. Local lymph node assays (LLNA) indicated negative for evidence of delayed dermal sensitization. Ames test evaluation by independent clinical testing (unpublished) in five salmonella strains indicated dechloro ethylcloprostenolamide is nonmutagenic. Ocular safety testing at an independent IRB-approved testing site by an ophthalmologist was conducted with four-week use in contact lens wearers, noncontact lens wearers, and individuals with self-assessed sensitive eyes. Individuals underwent serial ophthalmologic exams and questionnaires. No ophthalmic or ocular adverse effects were observed. There was no measurable change in intraocular pressure. It was concluded that the test material did not demonstrate a potential for eliciting ophthalmic irritation and is clinically safe. Safety study revealed no change in intraocular pressure, lacrimal duct, and conjunctiva, and was deemed safe for contact lens wearers and those with sensitive eyes.

c. Study:

In Choy et al., subjective reports by users of MD Lash Factor to improve the appearance of eyelashes—especially in regard to increasing length—was assessed (1). A randomized, double-blind, clinical trial was conducted with 34 healthy volunteers randomly assigned to one of three different treatment groups. These groups consisted of varying concentrations of the key ingredient (dechloro ethylcloprostenolamide, a novel synthetic topical prostaglandin analogue) and a placebo group. **Results:** All treatment groups demonstrated a statistically significant increase in eyelash length after four weeks of daily use. Group A: 1.69 mm, Group B: 1.94 mm, Group D: 1.44 mm and Group C (placebo): 0.63 mm. Twenty-four percent subjectively reported an increase in the thickness or fullness of their eyelashes. There were no complications. Fifteen patients reported minimal initial transient irritation. No discoloration was noted. **Conclusion:** Subjective reports by users of improved appearance in their eyelashes were confirmed. Use of dechloro ethylcloprostenolamide had minimal side effects.

Table I. Summary of results.

	Pre-application	After 4 weeks of application			
	Mean lash length±STD	Mean lash length±STD	Change in lash length (range)	% Change (range)	p-Value
Control group A, $n = 34$	3.46 mm±1.03	5.15 mm±1.13	1.69 mm (0–4.3)	49% (0–145)	8.78×10^{-8}
Group C (Placebo), $n = 11$	3.10 mm±0.70	3.73 mm±0.64	0.63 mm (0.1–1.5)	20% (3–51)	1.0×10^{-2}
Group B, $n = 14$	3.69 mm±1.15	5.63 mm±1.25	1.94 mm (0.2–4.2)	53% (3–156)	9.50×10^{-6}
Group D, $n = 9$	3.42 mm±1.12	4.87 mm±0.95	1.44 mm (0.4–2.0)	42% (10–87)	1.32×10^{-5}

d. Discussion:

The hypertrichotic properties of topical prostaglandin analogues used in the treatment of glaucoma have been well described in the literature (2–6). Elgin *et al.* (6) describe a 0.67 mm mean increase of eyelash length in 20 adults after six months of latanoprost therapy. Similarly, Sugimoto *et al.* (2) report a significant quantitative increase in eyelash length (0.7–0.8 mm) after two to ten weeks in 17 patents treated with latanoprost for glaucoma. Johnstone and Albert (3) also describe a greater thickness of eyelashes and additional lash rows as well as an increase in the length of lashes with topical latanoprost. Prostaglandin analogues used in these studies were in the form of ophthalmic drops. In Choy *et al.* study (1), the novel topical prostaglandin analogue, dechloro ethylcloprostenolamide, was applied directly to the eyelash roots, resulting in a significant increase in eyelash length at different concentrations of the active product as well as a subjective enhancement of eyelash thickness in 24% or the patients. The absolute and relative increase in eyelash length observed with dechloro ethylcloprostenolamide was greater than that reported in the literature with ophthalmic preparations.

Iris pigmentation and darkening of the periocular skin are reported as rare side

effects of topical ophthalmic prostaglandin (7–10). Neither of these side effects was observed in patients using dechloro ethylcloprostenolamide. Abelson *et al.* (11) describe hyperemia with topical ophthalmic bimatoprost peaking one day after the first instillation and returning to near-baseline levels with continued use. Only one patient reported moderate irritation and discontinued the product, whereas 15 patients reported mild irritation with the use of dechloro ethylcloprostenolamide. However, this mild irritation was transient and in most cases resolved within a few day of use.

Latanoprost has been described in the treatment of alopecia areata for cutaneous use and eyelash formation (12, 13). One of the study patients had alopecia areata. This patient was in a prior study for four weeks using topical ophthalmic bimatoprost on lashes with minimal eyelash enhancement. After four weeks of topical dechloro ethylcloprostenolamide, a significant increase in eyelash length (100%) was observed. Furthermore, four months of follow-up data were obtained in 21 patients who continued to use the active product daily and exhibited a mean increase in eyelash length approaching an 80% increase from baseline. During first year of use of dechloro ethylcloprostenolamide in MD Lash Factor in 70,000 patients, no confirmed serious adverse reaction or iris discoloration was noted. The mechanism of action is unknown.

e. Newer-Generation Lash Conditioners:

Second-generation prostaglandin-free formulations have produced similar effects to an earlier prostaglandin formulation, with consumers generally noting longer usage duration needed to achieve noticeable efficacy. Active ingredients are cytokines/bioactive peptides, antioxidants, prostagladin precursors, and vitamins. Recently, a novel class of peptides derived from adipose-derived stem cells has been developed with no published data yet available on efficacy.

f. Observations with lash conditioner usage:

Users of lash conditioners will note new hair emerging from areas where one typically does not have lashes, such as the medial and lateral corners of eyes folds. Users with light lash colors will first note increase in length and thickness of lashes followed by color within the lashes. In our monitoring of 70,000 patients during the first year of use in all ethnicities, three cases of Hispanic users noted lashes falling out during first two months of use with a gradual return of lashes over a two-month period. This is likely due to catagen follicles entering the anagen phase. No confirmed iris pigmentation changes were

reported in 70,000 patients in 2009 by this author.

Similar hair enhancement has been noted from lash conditioner on brows and scalp. An independent clinical testing facility conducted open enrollment of 30 healthy subjects (50% male and 50% female) ages 18–45 with men with grade II–III Hamilton and women with grade I–2 to I–4 Ludwig classification. Dermatologists ruled out chronic skin issues, concurrent hair loss treatment, or treatment known to cause hair loss within six months. Follow-up was made at 42, 84, and 121 days. Data analysis of self-evaluation and photos was taken. Data analysis of self-evaluation involves establishing frequency tables to each qualitative question. Two percentages Z1 and Z2 are calculated as follows: Z1 = favorable opinion (Ex: "Completely agree" + "Somewhat agree"); Z2 = unfavorable opinion (Ex: "Completely disagree" + "Somewhat disagree"). The statistical difference in frequencies between favorable and unfavorable opinion is evaluated using the Chi-squared test at 5%.

g. Results:

1. 88% agreed that there were little to minimal discomfort while using the product.
2. 96% felt product was easy to apply.
3. 71% agreed product helped with hair growth with 17% noted improvement at four weeks, 38% noted at eight weeks and 8 % noted at 12 weeks.
4. 50% agreed product helped with thickness of hair.
5. 63% agreed improved volume of hair.
6. 46% agreed improved softness of hair.
7. 75% would recommend product.

CONCLUSION:

MD® Follicle Energizer showed subjective findings of improved hair appearance and user acceptance. This material may be considered as an adjuvant treatment to concurrent hair loss therapy.

FUTURE DEVELOPMENT:

Usage of proteins secreted by adipose-derived stem cells

A Question for Thought and New Directions in Hair Growth Products:

"Given the rich stem cells residing in hair follicles, is it feasible to

generate new hair follicles?"

A first attempt at arriving at an answer to this provocative question lies in the following quote from the American Journal of Cosmetic Surgery by *Hirotaro Fukuoka, MD, PhD; Hirotaka Suga, MD, PhD; Keigo Narita, MD; Rei Watanabe, MD; Satoru Shintani, DDS, PhD:*

"Scalp hair was noted to regenerate after topical application of such a protein."

The author's preliminary data on injection of stem cell–derived purified growth factors yielded interesting results after one treatment in four weeks in scalp hair. Such a regimen may be feasible for lashes and eyebrows as well.

ABSTRACT

This chapter discusses the structure of nails and describes in detail various abnormalities that may occur. Since nails and their appearance are a significant

part of beauty/cosmetic care, it is important to understand the various issues that make nails unsightly and what can be done about them. The discussion also focuses on the potential effects of various chemicals used in nail beautification and provides critical thinking directions for improving nail appearance.

3.4.1 INTRODUCTION -TOENAILS AND FINGERNAILS

The primary function of toenails and fingernails is to protect the distal aspect of the digits. They protect the bones and surrounding soft tissues from injuries.

They enhance tactile sensation to the digits. Nails are also used as a tool to increase precision gripping of small objects by human beings.

a. Fashion

Originally, polishing of the nails dates back to 3000 BC in China and later in Egypt. The color of the nail polish symbolized social classes [1]. The modern history of polishing the fingernails and toenails as a fashion statement dates back to the beginning of the 19th century. Oils, powders, and creams were applied to the nails and the nails were buffed, leaving them shiny [2]. Today, most nail polishes are derivatives of pigments in solvents.

b. Function

The nails are located at the distal ends of both the fingers and the toes on the dorsal aspect. Their maintained function is to protect the digits from trauma [3]. The curvature of the nail helps to define the shape of the distal end of the digits. Although there is a complete absence of nerve endings inside the nail, nails enhance the tactile sensation of the digits with pressure on the surrounding soft tissues and their nerve endings. This property, along with their useful ability to grip small objects, allows humans to have a more precise use of the fingers.

c. Anatomy

The "Nail Unit" consists of the following parts:

- Nail plate (*Corpus Unguis*)
- Nailbed
- Medial nail groove
- Lateral nail groove
- Distal nail groove (*Hyponychium*)
- *Epionychium*
- Posterior nail groove (Cuticle)
- Nail root (lunula, Matrix, Matrix Unguis)

The nail plate is the actual hard part of the nail. It is made of the tough protein keratin. *Unlike the keratin of skin*, the nails do not peel off in the form of scales. The keratin of nails also contains a much lower lipid content than skin, which allows much less water flux across the nail.

The nailbed in the skin below the nail plate contains living dermal tissue, which includes capillaries and glands. This vascular area gives the nail plate a pink appearance where it is adhered. At the distal end, the nail plate appears

whiter in color where it is separated from the vascular nailbed.

The medial and lateral nail grooves form the indentation on the lateral borders of the nail plate. They are sometimes called the nail folds.

The distal nail groove, called the hyponychium, is at the end of the digit where the epithelium of the skin meets the nail plate. It forms a seal that protects the nailbed from infection and trauma.

The epionychium is a thin band of epithelium that connects the nail plate to the proximal skin.

The posterior nail groove, called the cuticle, is a thin layer of epithelium that extends from the skin over the epionychium and the proximal end of the nail plate.

The nail root, also call the nail matrix, is the germinal tissue that is responsible for producing cells that become the hard nail plate. The nail root extends 5–10 mm proximal to the posterior nail groove. The visible part of the nail root beyond the skin is called the lunula and appears as a half-moon-shaped, lighter-colored region at the proximal part of the nail.

d. Development and Formation

The earliest signs of fingernail development appear in the ninth week in utero. Fingernails and toenails develop by the same process; however, toenail development is slightly slower and about four weeks behind that of fingernails.

Skin folds and grooves begin to form at the distal end of the fingers and will eventually define the structure of the nail unit. The first structure to appear is the matrix at week 11. By week 20, matrix cells exhibit adult keratinization.

At the week 32 a hard nail plate of the finger is formed. At birth, a long thin nail plate is present, which overhangs and curls over the distal digit.

In the discussion of nail formation, one must look at each component of the nail unit and what it contributes. The proximal nail fold is the wedge-shaped structure on the proximal edge of the nail unit. Its dorsal side differentiates to normal epidermis, while its ventral side differentiates to form the cuticle, which adheres to the dorsal surface of the nail plate.

The hyponychium is similar in that the distal portion contributes to the normal epidermis of the volar skin, while the proximal portion helps in adhering to the nail plate.

The matrix differentiates to form the nail plate as we know it. It occurs by specialized tissue kinetics, as described by Zaias [4], who showed this in

monkeys and rats by introducing a radio-labeled marker; this was later confirmed by Norton [5] in humans. These studies materially advanced our understanding of matrix kinetics.

The nailbed epithelium differentiates both in an upward and a lateral motion. The upward growth produces specialized epithelium, which adheres in a special interconnecting manner to the developing nail plate, thus aiding in the adherence of the nail plate to the nailbed.

The lateral growth of the nailbed epithelium is toward the distal edge and moves at the same rate as the nail plate formation. Other authors have suggested different theories of nail plate formation, included here primarily for historical reasons [6, 7].

The matrix lies flat in the proximal nail unit. It produces a sheet of onychocytes (corneocytes), which grow diagonally along its entire length and move distally in a contiguous fashion. This development of multiple sheets of onychocytes eventually forms the nail and produces the dorsal surface of the nail plate; the midportion of the matrix produces the midnail plate; and the distal portion produces the ventral surface of the nail plate. Based on this anatomical arrangement, it can be concluded that the thickness of the nail plate is directly related to the length of the matrix.

A disruption of any of the processes discussed earlier will produce specific diseases of the nail at specific sites, which will be discussed later in this chapter.

3.4.2 HISTOLOGY, ULTRASTRUCTURE, AND COMPOSITION

The epidermis of the proximal nail fold is similar to the normal epidermis dorsally except that it is devoid of adnexa (sebaceous glands, eccrine glands, hair, arrector pili muscle), while ventrally it produces the cuticle. The epidermis of the nailbed is similar to that of the skin, but has no stratum lucidum or stratum granulosum layers and no hair follicles or sweat glands. There is a unique arrangement of the dermal papilla and rete ridges, which form a parallel pattern in the nailbed and interconnect in a tight fingerprintlike pattern to the nail plate. The nailbed moves forward with the growth of the nail plate [4, 5]. The epidermis of the matrix is thick and passes into the substance of the plate, which is formed by changes similar to keratinization in the epidermis; however, the end product is nail plate instead of stratum corneum.

The appearance of the lunula probably reflects incomplete keratinization in the

matrix just before incorporation into the nail plate [8]. The nail plate is made up of impacted and adhering layers of flattened cornified cells (dead onychocytes) that have lost their nuclei. The cells contain hard keratin, similar to that of hair with a high sulfur content mainly in the form of cystine, which comprises about 9–12% of the weight of the nail.

The keratin fibrils are primarily oriented parallel to the nail surface from side to side. The nail typically contains about 7–12% of moisture and 0.15–0.76% of fat, a little more (1.38%) in infants. The composition of the nail plate varies slightly from the early *in utero* plate to that in adults. Baden [9] showed that water content of the nail plate is related to environmental relative humidity. Calcium constitutes about 0.02–0.04% of the weight and does not contribute to the hardness.

Other trace elements have been detected and measured in nail clippings. The nailbed and matrix have a rich supply of blood from two arteries that run laterally along the digits and form oxygen-rich capillary beds, which lie below the nail plate [3, 8].

3.4.3 RATE OF NAIL GROWTH

Nails, unlike hairs, grow continuously throughout life. The rate of growth of the nail plate is determined by the turnover rate of the matrix cells. Early measurement of the growth rate in undergraduates and schoolchildren were made by notching the nail about 2 mm from the margin of the lunula and recording its progressive displacement in each succeeding month. No differences were found within the age range of 19 to 23 years, no sexual difference, and only a very slight difference between hands, with growth on the right being faster. However, there were differences between fingers, growth being fastest on the third digit and least on the fifth finger. Bean [10] studied his own thumb for over 30 years and found growth to be faster during the second to third decades, followed by a slowing-down trend and then a leveling-out over time. The rate of fingernail growth varies between 0.5 and 1.2 mm per week. Fingernails grow faster than toenails which vary between .2 and .4 mm per week. Family tendencies favoring similar growth rates have been noted, as well as increased growth during the summer and diminished growth in cold climates. Certain conditions affect the rate at which the nail plate grows. On average, it is higher in psoriasis, pregnancy, and nail-biting trauma. Regrowth is temporarily depressed in infective diseases, particularly in viral conditions such as measles

or mumps, yellow nail syndrome, and starvation [3]. To replace a fingernail completely takes about five to six months; toenails require 12 to 18 months.

3.4.4 NAIL PATHOLOGIES

Abnormalities of structure and appearance of the nails are more than cosmetic. Many work hours are lost each year due to absenteeism of patients who suffer from nail disease. There are many causes of nail disease: genetic factors, hereditary factors, infection, inflammatory, environmental, traumatic, secondary to systemic disease, biomechanical considerations, and idiopathic as well as the effects of aging. Skin and nail changes begin to occur as people age. During the aging process, the fingernails and toenails have been shown to thicken and show a slowing ingrowth while becoming more susceptible to diseases [11]. Nail problems also occur during pregnancy and consist of transverse grooves, increased brittleness, softening, and no separation [12].

Diseases and disorders of the nails can be classified into conditions according to: maladies peculiar to the nails themselves, onychodystrophies, nail manifestations of dermatitis, nail manifestations of systemic disease, and congenital condition of the nails. Disease also can be grouped into different classifications according to the type of disease, including: infection, psoriasis, contact dermatitis, eczematous dermatitis, hypo-vitaminosis, tumor, trauma, and genetic disease.

Only the most common conditions are discussed here, but readers may consult complete texts such as Scher and Daniel [8] for a comprehensive account of the various conditions that affect the nail unit.

a. Absence of Nails (Anonychia)

Complete absence of nails from birth, anonychia, is rare and appears to be associated in several ways with other congenital, hereditary defects. Absence of nails may be individual, multiple, or total in some congenital conditions. Loss of nail plate may occur with some inflammatory conditions such as lichen planus and irritant dermatitis to artificial nails, or secondary to trauma.

b. Nail Shedding (Onychomadesis)

Nails can be lost either by loosening at the proximal end or by separation from the nailbed. Shedding can follow trauma or severe illness or can be caused by drugs. More serious loss with scarring sometimes follows trauma, defective

circulation, lichen planus, epidermolysis bullosa, or drug eruptions.

c. Nail Separation from the Nailbed (Onycholysis)

The separation of the nail from its bed is fairly common. There are many causes, but quite often none can be found. Nail separation may result from external damage both traumatic and self-induced, that is, overaggressive cleaning, fungal and yeast infections, acute and chronic dermatitis, or drug eruptions. Various conditions such as psoriasis, tumors, and many genetic disorders can also cause onycholysis [3, 8]. Of particular interest are reports of onycholysis caused by cosmetic products [13, 14] and the use of acrylic [15] or artificial nails that cause a contact or irritant dermatitis leading to nail separation [16]. Nail hardeners containing formaldehyde [13], nail varnish containing phenol, ultraviolet nail dryers [17], and similar agents have all been implicated. Once onycholysis is present it is not unusual for colonization by either a Candida sp. or Pseudomonas sp., giving the nail a yellowish or green color, respectively. Often onycholysis is treated by removing the distal part of the nail that is not attached to the nailbed. This is usually a painless procedure. Once the separated nail is removed, emollients are applied to the nailbed and distal end of the nail plate daily in order to soften the skin and nail and to get the nail to reattach to the skin as it grows distally.

d. Brittleness

Brittle nails are among the most common cosmetic complaints. The phenomenon tends to occur in advancing age. While sometimes they may be associated with some underlying conditions, no good data are available, and the causes are mostly not known but are known to be related to nutritional disturbances, thyroid disorders, and skin conditions. Environmental factors are certainly important. Nails are kept pliable by their moisture content, and long thin nails are especially susceptible to very dry climates. Frequent immersion of the hands in surfactant solution is conducive and some time ago it was believed that soaps and detergents removed the protective lipids from the keratin. The continual use of nail varnishes and varnish removers have also been blamed [8]. Almost 60 years ago the reactions of 25 businesswomen to the same brand of nail lacquer were studied. It was found that nearly half of them showed brittleness and splitting of the nails while the rest were unaffected. Thus, there is no support for attributing nail brittleness to the use of conventional nail lacquers. Some investigators have reported improvement with gelatin and application of essential oils, but no

consistently effective therapy is known. Other researchers recommend avoidance of frequent immersion and nightly use of emollients.

e. Striations (Onychorrhexis)

Longitudinal striations are common in healthy nails and become more prominent with aging, and other clinical or occupational conditions such as lichen planus, psoriasis, and trauma. More prominent longitudinal ridging is seen in median nail dystrophy, which is attributed to habit tics (self-induced behavior). Transverse, horizontal striations can occur as a developmental anomaly. Severe depressions, known as Beau's lines, indicate a period of severe systemic disease, such as measles, mumps, pneumonia, rheumatoid arthritis, myocardial infarction, pulmonary embolism, high fever, or coronary thrombosis. Drugs may also induce inhibition of normal matrix production of nail plate. They can also be caused by trauma. Thinning of the nail plate is seen as secondary to decreased peripheral circulation, lichen planus, iron deficiency anemia, and epidermolysis bullosa.

f. Spoon-Shaped Nails (Koilonychia)

In koilonychia or spoon nails, the nails are thin, soft, and concave in the center. The condition results from iron-deficiency, and is usually, but not invariably, associated with anemia. It can also be seen in onychomycosis and has been noted in motor mechanics, where, perhaps, it is due to softening as a result of the use of oils or soaps. This condition may also be seen as a temporary disorder in young children and is also a cemented congenital anomaly. Plummer-Vinson syndrome (a combination of koilonychia, dysphagia, and glossitis) is primarily seen in middle-aged women and is also called Plummer's nails.

g. Splitting (Onychoschizia)

The splitting of nails horizontally, parallel to the nail plate, so that pieces of the surface break away, is very common in women and in advanced age. The main causes are probably repeated immersion in water and the use of nail polish and polish removers. The suggested treatment is to rub emollients into the nail plate after bathing and avoid frequent use of nail polish and removers.

h. Pitting

Pitting of the nails is found most commonly in psoriasis. Pits represent punctuated or depressed sites in the nail plate secondary to irregular matrix

production. They can vary in size, shape, depth, and number. Pitting is the most common manifestation of nail psoriasis [21] but can also be seen in chronic dermatitis, fungal infections, alopecia areata, Reiter's syndrome, lichen nitidus [22], and lichen planus. Minor degrees of pitting may be seen in healthy nails, and when no other skin complaints are present, they are considered to be normal variants.

i. Leukonychia

Leukonychia is complete or partial whitening of the nail plate and can be divided into acquired and congenital types. Complete leukonychia occurs very rarely as an inherited abnormality; often, epidermal cysts on the glabrous skin are associated with it. Partial leukonychia is very common and may take the form of white spots or white transverse streaks. It may be associated with many types of illnesses, exposure to chemicals, and traumatic events to the matrix. A white appearance of the nails is not necessarily due to leukonychia; it may result from changes in the nailbed, not in the nail plate.

j. Onychomycosis

Fungal infections of the nail unit are the most common conditions affecting nails. There are four distinct types of clinical presentation: distal subungual, superficial white, proximal subungual, and candida albicans onychomycosis. Distal subungual onychomycosis is the most common type and has been shown to be an autosomal dominant inherited condition in the chronic dermatophyte syndrome. The discoloration begins at the distal edge of the nail and spreads proximally. Onycholysis begins with thickening and irregularities of the nail plate and causes it to separate from the nailbed; subungual debris begin to accumulate in secondary bacterial infections. Proximal subungual onychomycosis starts at the proximal nail fold. It often begins as a small white area located proximally on the nail plate and subsequently enlarges and spreads. Superficial white onychomycosis produces a white powdery appearance. Candidal onychomycosis is usually seen in patients with mucocutaneous candidiasis syndrome. It begins by directly invading the nail plate itself rather than extending onto the nail from the adjacent skin. It is much more prevalent in the toenail than the fingernails.

k. Paronychia

Paronychia is defined as inflammation of the proximal or lateral nail folds or a

combination of the two. Paronychia occurs after loss of the cuticle either by trauma or by aggressive cuticle trimming or cuticle pulling. It can be acute or chronic. Acute paronychia is caused by introduction of an infectious agent into the nail folds, usually through trauma, ingrown nails, cuticle pulling, or exposure to an irritant agent. Paronychia with bacterial infections often needs medical attention to drain the infection and remove the ingrown nail as well as treating with antibiotics. Chronic paronychia occurs over time due to continual exposure to an irritative behavior, chronic ingrown nails, constant exposure to water from hand washing, or a specific contactant such as food items or chemical irritants.

l. Discoloration

Nails may be discolored for a wide variety of reasons. External causes include hair and other chemical dyes, smoking, and chemical compounds such as mercury salts, dithranol, and picric acid. Tints may leak out of nail varnish and after repeated use may penetrate the nail [17–20]. The use of artificial nails and either acrylic or pre-formed plates can cause discoloration. Abnormal formation or very slow growth of the nail can also produce color changes. Psoriasis and onychomycosis, among other abnormalities, cause opaqueness and a yellowish discoloration. In the “yellow nail syndrome” the nails almost cease to grow and several months later become yellow or greenish. They may also be thickened and curved from side to side. Yellowish, green, or gray nails can also occur as growth of nails slows down in old age. Infection by *Pseudomonas aeruginosa* under the nail may cause a greenish, black, or blue discoloration. Systemic drugs can alter the color in many ways. Prolonged administration of tetracycline may occasionally turn nails yellow. Mepacrine or Zidovudine (AZT) makes them bluish black, and chloroquine may produce blue-black pigmentation of the nailbeds.

The pigmented discoloration or pigmented bands are the most important types to distinguish. Although most pigmented bands seen in nails represent benign lesions, such as nevi or traumatic or splinter hemorrhages, one must always be suspicious of pigmented bands that are malignant, such as malignant melanomas. Any new onset or rapidly changing pigmented band in the nail should be evaluated by a dermatologist for possible biopsy. Early diagnosis can save serious sequelae of malignant melanoma.

m. Subungual hematoma

Subungual hematomas may cause the collection of blood underneath the nail

plates. It is often associated with acute trauma. When associated with acute trauma, there is often severe pain from the pressure of the blood underneath the nail. Subungual hematomas can also occur more slowly with repetitive trauma. Often these are not painful at all. This is often seen in runners and dancers.

Accessing the Biology of Human Olfaction: New, All-Natural Fragrance Ingredients; Novel Consumer Fragrance Experiences and Applications

by

Kambiz Shekdar, Visiting Scientist, Rockefeller University

ABSTRACT

Contemporary fragrance creation

Contemporary fragrance ingredient discovery and fragrance creation relies on sensory testing and evaluation methods by humans. Perfumers or experts discover new fragrance ingredients and they create new fragrance formulations while human sensory studies comprising panels of nonexpert or naïve human subjects are used for further evaluation. Whereas contemporary fragrance creation methods have been developed over decades and are considered the gold standard precisely because of their central reliance on humans, recent trends suggest that this process alone may soon become obsolete due to its lack of speed and throughput. First, consumer demand for products that are all-natural, economic, and sustainable is growing. In some consumer applications, synthetic ingredients have become a mainstay in the fragrance industry. At the same time, it is only becoming harder to identify natural fragrance ingredients that can be sourced reliably. Many natural ingredients are sourced from equatorial regions that are forecasted to suffer most severely from global warming and political instability. As a result, pressure for the rapid and reliable discovery of new, all-natural fragrance ingredients is increasing. In order to discover new fragrance ingredients for all-natural and sustainable products, new discovery methods that enable rapid and reliable testing of hundreds of millions of ingredients and extracts are required.

Next-generation fragrance creation

Borrowing from the fields of cell biology and drug discovery, the application of

cell-based high-throughput screening (HTS) methods stand to enable the rapid and reliable testing of hundreds of millions of ingredients and extracts to aid in new fragrance ingredient discovery. Biologically, the sense of smell in humans is mediated by a family of ~350 odorant receptors. In principle, laboratory cells can be created to comprise odorant receptors. These cells could then be used as miniaturized detectors for “turbo smell testing” in cell-based assays to detect new fragrance ingredients. Ingredients identified as active in the cell-based assays could then be evaluated in human sensory studies or by perfumers. Importantly, the success or reliability of any cell-based assay depends on how closely it is produced to mimic the natural or native biology of the receptor it is designed to comprise. Recent advances in the science of cell-based assay creation reported across receptor classes—including drug, taste and odorant receptors—suggest that it is now possible, for the first time, to produce these assays such that they mimic the physiology of their intended receptors to a much greater degree than had been previously possible. In the context of olfaction in which such an especially large number of receptors are implicated, the advent of physiologically relevant cell-based assays in combination with expert and naïve human sensory methods will allow more rapid and reliable fragrance creation.

In this chapter we review:

(i) the background on the biology of olfaction and the sense of smell

(ii) the basic design and principles of miniaturized cell-based assays for high-throughput odorant ingredient discovery

(iii) novel classes of previously inaccessible natural fragrance ingredients that stand to alleviate the emerging bottlenecks, including natural ingredients that augment, diminish, or otherwise modulate the sensory profile of fragrances, and the forward-looking and previously unknown applications that these enable, and

(iv) recent understanding of the biology of odorant receptors as it relates to the creation of a fragrance-discovery engine with unprecedented high fidelity to the natural sense of smell.

In addition to facilitating the discovery of new natural ingredients and combinations of ingredients with desired aromatic properties, a systematic cell-based discovery engine could produce new fragrance ingredients for more precise further investigation of the biology and basis of human olfaction as well as create novel consumer products and applications. All in all, the advent of a rapid and reliable odorant ingredient discovery engine could open the gates to a whole new world of aroma research and product development.

3.5.1 ODORANT RECEPTORS

Odorant receptors (ORs) are the biological entities that mediate the detection of scent. In humans, a family of at least ~ 350 genes encoding ORs has been identified. (1) This family or group of ORs are G-protein coupled receptors, or GPCRs. GPCRs are a classification of protein molecules localized in the outer membranes of cells. The ~350 ORs are integral membrane proteins; they traverse the cell membrane and comprise domains that are intracellular, transmembrane, or extracellular. While it is thought that certain odorant molecules may penetrate the cell membrane to impart their activity by interacting with transmembrane domains of the ORs, it is generally thought that it is the extracellular domains of ORs that mediate the detection of odorant molecules, as these domains would be most accessible to volatile compounds in the nasal cavity.

The ~350 GPCRs that have been described as odorant receptors are defined as such based both on their sequence homology and relatedness as well as their expression in cells that line the nasal epithelium. However, not each of these ORs has been confirmed as an odorant receptor. In addition, it is possible that other receptors in the nasal cavity and elsewhere may also play a role in human olfaction.

It may be helpful to think about the large family of ORs as the keys of a piano keyboard, where some odorant molecules will hit or activate one single receptor, or key, essentially sounding off one single aromatic note, whereas other more complex ingredients or substances may hit an entire chord, or several odorant receptors, all at once. Depending on which ORs are activated and how strongly,

a different smell may be experienced or perceived in the brain.

3.5.2 CELL-BASED HIGH-THROUGHPUT ODORANT DISCOVERY'PRINCIPLES AND BASIC DESIGN

Cell-based high-throughput screening of ORs

High-throughput cell-based screening of ORs requires laboratory cells that are treated to comprise ORs. Typically, for any given OR, a gene encoding the OR must first be introduced into cells, and the OR that is encoded must be synthesized by the cell and transported to its outer (plasma) cell membrane, or cell surface. The preparation of cells used may be transiently transfected cells or they may be stable cell lines. Transiently transfected cells refer to populations of cells that are freshly introduced with the gene encoding the OR, where a new batch of cells is produced each time, as required for testing. Stable cell lines refer to clonal populations of cells where a single cell introduced with the OR gene is selected and used to create a clonally prepared population of genetically identical cells. The advantage of using transiently transfected cells includes speed, as the time required to produce a stable cell line is not necessitated, whereas the advantage of using stable cell lines includes identification of a population of cells with desired and well-characterized properties. There are many methods available to achieve either transiently transected cells or to produce stable cell lines, and these must be carefully considered given the host cell type used and the gene to be expressed in order to achieve the most physiologically relevant cells and assays. In this chapter, data for the use of stable cell lines are presented.

In addition, creation of laboratory cells that comprise ORs that function as they do in their natural setting *in vivo* is challenging. The cells of the nasal epithelium that typically express ORs *in vivo* are highly specialized, polarized cells that are not approximated by typical laboratory cell cultures, which comprise cells derived from various tumors or are otherwise immortalized. Current methods for the production of cells suitable for HTS of ORs are described in the last section of this chapter. Once cells comprising the OR are produced, a cell-based assay that can be used to monitor the activity of the OR must also be produced. The activation of many classes of GPCRs, including ORs, results in an influx of calcium into the cytoplasm or interior of the cell. Therefore, the use of fluorogenic dyes that can be used to report the presence

and concentration of calcium is common. Figure 1 shows cell-based assay responses for a panel of eight cell lines, each comprising a different native and full-length OR (See Figure 1).

Figure 1 A cell based assay was used to test the activity of a set of 8 different ORs in response to an activating compounds. Dose response curves are shown. For each OR, a compound with an EC50 value of less than 100 µM is shown. The assay response (Y-axis) over time (X-axis) is shown.

High-throughput screening and discovery of new fragrance ingredients

Once a cell-based assay is created, it must be miniaturized to high-throughput format, where typically 384-well plate or 1536-well plate microtiter well plates are used to interrogate the activity of many different samples on the OR at any given time. As the testing of a plate requires on the order of one to five minutes only, hundreds of millions of extracts and ingredients may be tested on a 24-hour basis using standard automated and scalable screening instrumentation.

In HTS assays, it is important that the assay response is sufficient and consistent for reliable discovery of modulators. That is, in each well tested with an activator of the receptor, the signal-to-noise ratio of the response generated in the cell-based assay compared to buffer-only control must be great enough to enable reliable detection of either a modulator or blocker. In addition, this assay response must be consistent from well to well, to enable comparison of testing results for different compounds and ingredients across a plate. One common measure of the suitability of a miniaturized cell-based assay for HTS is the value for the Z´ Factor of the assay. The Z´ Factor of an assay is derived using an equation that takes both the signal-to-noise ratio and the well-to-well consistency of the assay response into account, with values ranging from 0 to 1. (2)

Typically, a cell-based assay with a Z´ Factor value of 0.4 or greater is considered suitable for HTS. Figure 2 shows OR cell-based assays with Z´ Factor values suitable for the HTS for the same set of eight receptors as depicted

in Figure 1.

Figure 2 The same set of ORs as shown in Figure 1 were miniaturized to 384-well plate HTS assay format. Responses for the testing of the 384-well plate assays with an activating compound (dark shaded) or buffer-only control (light shaded) are shown. Z' values of at least 0.4 were generated for each OR.

Once cell-based assays with a suitable Z´ Factor are established, the first step in discovering new odorant ingredients for a given application is to determine which of the panel of ~350 known ORs are relevant for the desired application. To do this, a panel of cells representing the entire family of ORs is exposed to the aromatic substance and the ORs that are activated in response to it are identified. To identify the ORs that correspond to the aroma of a rose extract, for instance, the receptors that respond upon exposure to the extract are selected. Aromatic substances like rose extract often comprise hundreds or thousands of aromatic ingredients. It is the combination of the aromatic or sensory profile of each ingredient that produces the net or perceived sensory experience or fragrance. Often, the key aromatic notes of a composite fragrance are derived from one or a few of these ingredients. Careful testing and analysis must be used to select the most meaningful set of ORs for HTS for any given aromatic substance of interest. Figure 3 shows the response of 320 compounds and extracts tested across the same set of ORs as shown in Figure 1 using the same HTS assay as shown in Figure 2.

Figure 3 320 test compounds were tested against the same set of ORs

as shown in Figure 1 using the same 384-well HTS assay as shown in Figure 2. Responses of the ORs to each compound are shown. **The assay response (Y-axis) over time (X-axis) is shown.**

An important consideration for fragrance discovery is that certain closely related natural extracts may be differentiated from each other by one or a few ingredients or notes. For instance, the extract from a particular subspecies of rose that is especially desirable compared to other rose extracts may be differentiated by the presence of one or a few particular aromatic constituents. By profiling the OR activity that is elicited across the entire panel of ORs for various rose extracts, those ORs that correspond to the unique aromatic notes of the preferred rose extract may be identified. In a next step, high-throughput screening using cell-based assays comprising these ORs may be used to identify new, natural ingredients that can be used to help replicate the aroma of the preferred extract. It may be that a number of different ingredients are required to activate the entire complement of relevant ORs.

Typically, a high-throughput screen identifies hundreds of prospective “hits,” or compounds of interest. Further testing and evaluation are then required to confirm which of these impart the desired fragrance experience in human sensory studies.

Sensory confirmation, iterative screening, and optimization

Once initial compounds of interest are identified in a high-throughput screen, human sensory studies are required to characterize the sensory properties of the compounds. For instance, in a screen designed to identify compounds that mimic the scent of a rose, the identified compounds would be tested compared to the gold standard using human subjects. Typically, compounds identified directly in a first round of screening must be improved upon to meet desired final characteristics. Ideally, a high-throughput screen yields compounds a significant percentage of which are confirmed in such downstream testing as having the desired or expected properties that would be predicted by the screen. The correlation between cell-based high-throughput assays and downstream assays is greatly dependent on the quality of the cell-based assays and the degree to which they are physiologically relevant detectors. Reliance on OR cell-based assays that comprise only full-length, native, and unmodified receptors is critical for this reason; any alteration of the native ORs could greatly diminish the physiological relevance of the resulting assay.

Regardless of the quality of the assay, more often than not additional testing and work are required to result in compounds that meet all technical success criteria. Even given a fully physiologically relevant screen, the compounds that are identified may have additional off-target activity or effects, such as activity on untested receptors or side aromatic notes. Sensory testing is therefore an important tool in prioritizing the hit compounds. In order to improve upon the compounds, additional rounds of screening may be necessary. Here, a library of compounds that includes compounds structurally or chemically related to the initial hit compounds is assembled and screened. Similarly, in the case that the initial hits are extracts, a second round of testing can include extracts related to the initial extracts. Iterative rounds of testing and downstream sensory evaluation can be used to find optimized derivatives of the original hits that most closely or exactly produce the desired sensory effect.

By designing the screening library to include extracts and ingredients derived from natural sources of unlimited supply or ones that are renewable, a limitless number of new compounds can be made available for iterative cell-based and human sensory testing. Each aromatic plant or substance often comprises thousands of volatile ingredients. Various preparations of these can be used to amplify the number of test compounds in the library. For instance, a library can contain extracts derived from a plant species where the plant species is cultivated under multiple different conditions or in various locations or geographies, or different parts of the plant can be extracted separately. In addition, the extracts can be treated in a variety of ways, including by heating, exposure to acids or bases, or incubation with enzymes to create even further chemical diversity. We can begin by limiting the library to natural ingredients that have a past history of human consumption and limiting its treatment to steps that are not industrial in nature. In a manner similar to cooking, or any other reaction that can take place in a common kitchen, we can provide access to the advantage that the included test substances will be generally regarded as safe, based on existing protocols for the assessment of safety. This, in turn, facilitates downstream human sensory studies, compared to novel or human-made compounds that must be extensively tested before they can be studied using human subjects.

The Extra Challenge

First and foremost, consider that in the case of odorant receptor biology and discovery, no fewer than ~350 receptors are implicated, where most cell-based

drug discovery relates to one or a handful of receptors. To navigate this space effectively, there must exist not only a robust cell-based discovery platform that is as comprehensive and physiologically relevant as possible, but expert sensory testing and input must be used to as a guide to calibrate, or "tune," the cell-based platform. In this connection, the analogy to the complement of ORs as keys of a piano keyboard is helpful. Imagine a complex aromatic substance or extract, for instance jasmine or mint extract. These substances may well interact with a large number of odorant receptors. In addition, some of the individual compounds contained in each extract may hit a cognate receptor hard and punctually, whereas other ingredients may exert their effect over time and more softly. A complete mapping of these substances across the entire known complement of ORs in addition to their known sensory attributes will be key to effectively understanding how to interpret the cell-based data generated during any discovery process. Access to the entire human olfactory system is required for effective discovery. Any effort at cell-based discovery that aims to rely on a representative subset instead of on all the known receptors carries the risk of missing important interactions.

3.5.3 NEW INGREDIENTS AND APPLICATIONS

Natural substitutes

In some fragrance applications, reliance is made on natural extracts that are of limited supply and high demand. In some instances, this has necessitated a shift towards the use of synthetic compounds and is in direct opposition to the expanding trend of sustainability and responsibility described elsewhere in this book. Often, it is challenging to exactly replicate the aromatic profile of the natural aromatic using the mixture of synthetics. In some cases there is a need for improvement, as consumer demand for the natural sensory experience is high and remains unmet. Furthermore, for natural fragrances that are in demand but of limited supply, development of new related fragrances is often impeded.

In this connection, the OR discovery engine may be used to identify new natural ingredients that can substitute for the original ingredients. In a first step, ORs corresponding to the desired aroma would be identified by exposing the panel to the aroma or to its signature components, if these are known.

Next, this subset of cell-based OR assays would be used in high-throughput screening to test millions of natural extracts, ingredients, and combinations of

these, in order to identify additional new ingredients that mimic the gold standard. Those ingredients that are identified may also have undesired characteristics. For example, such characteristics may have activity on additional ORs or undesired aromatic notes that are detected in downstream sensory testing. In these cases, additional rounds of iterative screening can be used. In each successive round, one would include prior hits in the library to be screened as well as a new set of test ingredients related to the original hits. For instance, if a substance in wild lily is found to partially mimic the desired scent of a rose but there is an undesired aromatic characteristic also, then the same wild lily, but cultivated in a variety of ways, may be used to prepare new libraries of extracts for testing. Additionally, a desired scent may be replicated, for instance, by combining two or more identified ingredients—each of which acts to impart a part of the aromatic profile of the gold standard.

Fragrance enhancers and fragrance blockers

Perhaps the most intriguing ingredients that stand to be discovered using a cell-based odorant discovery engine are fragrance enhancers and blockers. By definition, these ingredients work to modulate the sensory profile of other fragrance ingredients.

Using the analogy of music, a fragrance enhancer is defined as an ingredient that may or may not have its own aroma, which at certain concentrations, works to amplify or “turn up” the volume of a given desired fragrance or aromatic note. Similarly, a fragrance blocker is defined as an ingredient that can decrease or “mute” the smell of an undesired fragrance or malodor. Anecdotal examples of such ingredients have been known, often discovered randomly when a perfumer finds that one ingredient alters the sensory profile of other ingredients to which it is added. However, systematic discovery of such ingredients using perfumery alone has been challenging, as it is difficult to test any large number of random ingredients in combination with aromatic ingredients in order to identify those rare ingredients that can work as fragrance enhancers or fragrance blockers. The difficulty of accomplishing this is compounded by the fact that *any* molecule active on the odorant receptors can likely be expected to have an intrinsic odor of its own, as it is likely to interact with one of the large number of known odorant receptors. As such, classical methods would require thousands of test ingredients to be assessed, one by one, and at various doses against a key aromatic sample the sensory experience of which is desired to be amplified or muted. While skilled perfumers work to create fragrances, they are not machines

that can be used to test thousands of samples. Thus, the cell-based platforms for high-throughput cell-based discovery provide an approach to accelerating the effectiveness of perfumers in the design of a virtually endless supply of new fragrances.

In order to rapidly discover fragrance enhancers or blockers of a given aromatic substance, first the odorant receptors that correspond to that substance must be identified. In a next step, these odorant receptors would be exposed to the aromatic substance to record the response of the receptor. Next, test compounds would be added to monitor changes in this response. Because of the nature of high-throughput screening, hundreds of thousands of test ingredients could be tested at different doses per day. Such a process would allow the identification of those ingredients that work to either amplify or diminish the response of odorant receptors to the aromatic ingredient. These initial hits would then need to be further evaluated as described.

This approach can include a second round of testing using the high-throughput cell-based platform, for instance, to run dose-response studies. An ideal enhancer or blocker would be identified as one that increases or decreases the receptor activity at increasing doses of the test ingredient. Figures 4 and 5 show dose-response curves for fragrance enhancers and blockers, respectively, discovered using cell-based HTS.

Figure 4 Dose response curves for two potentiators each active on at least two ORs are shown. To generate the dose response curves, increasing concentrations of the potentiating compound (color plot) or no compound (dark plot) were tested on the OR in the presence of the same concentration of activating compound. EC50 values for the potentiators were calculated.

Figure 5 Dose response curves for compounds with blocking activity are shown. In the top panel, two different blockers each of which blocks the activity of one OR are shown. In the bottom panel, two ORs each blocked by the same compound are shown. Dose response curves are shown. IC50 values for the blockers were calculated.

Next, sensory studies would be needed to confirm the activity of the ingredients identified in the screen in human sensory studies. Sensory testing would also work to identify any unintended or undesired intrinsic sensory characteristics of these ingredients, or doses at which none are registered. Finally, once ingredients that are confirmed as active in human sensory studies are identified, the process is repeated. In each round, this is done by sourcing additional ingredients that are structurally or chemically related to the initial positive hits for an iterative round of testing and are designed to identify related ingredients with improved sensory profiles and characteristics.

Even with a high-throughput discovery engine, the systematic discovery of fragrance enhancers and blockers is still expected to be challenging. This is because of the large number of odorant receptors. Any ingredient must have activity across the entire subset of target receptors such that the desired sensory profile is experienced by a human subject, and no activity on any unintended receptors produces an undesired sensory profile or off-note. To discover those rare ingredients that act across the array of odorant receptors in exactly the manner that results in the desired sensory profile is no small order. Because the nature of high-throughput screening is such that it allows testing of millions of ingredients and combinations of ingredients, it is possible to identify hundreds of initial hits such that a systematic process for the discovery of final ingredients that meet all required criteria can be envisioned.

Again, the likelihood of success in any such attempt is predicated on the fidelity of the cell-based discovery process; that is, the odorant receptors that are provided for testing using cell-based assays must be accurate in *in vitro*

correlates of native odorant receptor function and physiology *in vivo*. This had been a challenge to achieve, until now.

Novel applications

The advent of methods for the systematic and reliable discovery of fragrance enhancers and blockers ushers in a new era for fragrance creation and a set of novel applications. A number of these are highlighted for illustrative purposes.

First and most basic, a fragrance enhancer can work to decrease the amount of a fragrance ingredient that is used in order to impart a desired aromatic profile. If a certain aromatic is limiting, less of it may be used. In cases where synthetic chemicals have been relied upon to mimic the sensory profile of a rare or prohibitively expensive natural extract or essence, often these fail to exactly replicate the gold standard. Fragrance enhancers, which can be limited to natural ingredients themselves, could be used in this case to enable reliance on the actual natural extract or essence only. This solution not only satisfies consumer demand for the use of all-natural ingredients, it also accomplishes a cost-saving as less aromatic is required.

Second, the discovery of fragrance blockers that can be used to block malodors including body or bathroom odor can be contemplated. Such ingredients can displace the use of strong, human-made chemicals presently used to mask such odors. Simultaneously, a consumer-friendly goal is reached in that the use of excessive chemicals may be curtailed. Perhaps of greatest interest to the perfumer, blockers of the aroma of body odor and of ingredients such as alcohol can eliminate these smells such that perfumes can be appreciated unadulterated by malodor or alcohol solvents.

Future potential

Perhaps most intriguing, the advent of reliable high-throughput discovery of aroma ingredients opens up entirely new applications for the cosmetic and personal care industries as well as many others. It is difficult to even predict what these may be. To capture the imagination, a number of possible future applications are described, many of which depend on progress in unrelated fields. First, many experts and laypersons alike have wondered whether emotions or moods that can be triggered by a particular scent have a biological basis. Is the smell of chamomile soothing and calming, or are we accustomed to thinking that it is? It is possible that using ever-advancing methods of brain imaging, more data can be generated to help us address these questions: Do we

see the same brain activity patterns in response to smelling a soothing aromatic as we do when in a state of calm? Do multiple calming aromas all result in the same brain activity? Does the smell of a forest of greenery evoke the same brain activity as images that we associate with freshness?

Diverse studies will need to begin to explore these questions, including brain imaging and also physiological and sensory studies. Methodologies for each of these will need to be refined and developed. However, the advent of high-throughput discovery of odorant ingredients provides one previously missing key element: for the first time, it could be possible to identify aromatic ingredients that are characterized as activating just a single or a very small subset of odorant receptors. The availability of such ingredients where the biological basis for their activity is defined provides a toolkit of reagents to probe the human response. Theoretically, all those receptors activated by chamomile could be identified, as well as aromatic substances that selectively activate each of these. Use of such aromatics in brain-imaging studies could be used to test whether any of these produce the calming patterns described. The availability of a cell-based HTS platform could allow the identification of such aromatic ingredients that could aid in the understanding of the biology and physiology of human olfaction in this and other applications. Imagine if it would be possible to find aromas that make us feel fresh and in a state of wellness and well-being.

At a more practical level, consider how unavailable or unreachable the sense of smell has been to the average person: Whereas, until now, we can play notes and music, or paint brush strokes and paintings, it has only been the trained perfumer who can truly “touch smell.” The advent of fragrance enhancers could be used to enable consumer access to the art of fragrance creation. A home stereo system, if you will, could be imagined in every home, where at the touch of a button the consumer would call to order various notes, like mint or sea breeze, all contained in miniature chambers. Small amounts only of hundreds of aromatics would be needed, as enhancers could be used to increase the activity of tiny doses. One could paint the mood of their home or room. If one creates a new fragrance, one could email the recipe to a friend for them to conjure it up in their own home, or a new fragrance that is released could be downloaded from a perfume website for easy sampling at home.

3.5.4 METHODS

In the preceding sections, the basic principles and design for high-throughput odorant discovery were introduced, and novel classes of aromatic ingredients that could be discovered have been outlined. For the first time, cell-based access to odorant receptors in their physiologically relevant form exactly as they exist in nature has been shown. The figures presented demonstrate the utility of this technology to access a subset of odorant receptors that represent the broad diversity of odorant receptors *in vivo*. Most significantly, these data point to the need of working with cell-based assays that exactly mimic native receptor biology and physiology as the bedrock and fundament for any cell-based discovery engine that utilizes cell-based assays. Taken together, the following were demonstrated:

1) Cell-based assays comprising native full-length odorant receptors can now be created.
2) This has been done for a panel of odorant receptors representing the various classes.
3) Cell-based assays suitable for high-throughput screening were developed.
4) Fragrance enhancers were identified.
5) Fragrance blockers were identified.

In this section, the state-of-the-art will be reviewed. Briefly, the odorant receptor biology field is rich and diverse, with hundreds of laboratories both academic and commercial exploring various aspects of odorant receptor biology. The purpose of this section is to outline the one key bottleneck that had existed, and to review recent advances that have overcome this limitation: Until very recently, it had not been possible to express odorant receptors in their native and intact form, exactly as they exist in nature, in the context of laboratory cells required for use in HTS. It has been reported that this is because in these cells, any OR that is expressed becomes trapped in the ER compartment of the cell. (3,4)

To by-pass the difficulties that were encountered, most laboratories have largely relied on one of two methods to enable expression of odorant receptors in cells: Either the receptor is truncated, for instance by cleaving off residues from one or both ends, or the receptor is extended, by adding additional residues that facilitate its expression in laboratory cells.(5, 6)

Though never desirable, these alterations were necessitated to achieve any cell-surface expression at all. It had been hoped that these alterations were otherwise benign; however, absent native odorant receptor cell-based assays, the testing to confirm this was lacking. Moreover, it is not unreasonable to question

that alterations that make the gross difference of enabling a receptor to be expressed at the cell-surface in the first place have only this desired effect—to facilitate laboratory practices and no unintended consequences. The risk had always been that though accessible, these altered receptors represent mutants that have little if anything to do with native odorant receptor biology or function.

Conversely, consider that odorant receptors are normally expressed in highly specialized cells in the nasal epithelium. These cells are not the same as the ordinary laboratory cells that are commonly used in the creation of cell-based assays. Attempts to express odorant receptors in average laboratory cells may have been challenging because of the fact that while these cells are often cancerous cells of various tissues that are used because they are hardy and grow well in the lab, they may not provide important but as yet unknown factors for proper expression and function of odorant receptors *in vivo*. As laboratory cells are populations of genetically divergent and not genetically identical cells, however, it may be possible that they include rare and unique genetics that enable expression of receptors that are otherwise inaccessible in their native and full-length form.

Indeed, a technology was reported that enabled the rapid testing of millions of cells for the isolation of rare cells capable of expressing full-length and native receptors, including odorant receptors and other receptors that had been previously out of reach in their native and full-length form. (7)

The platform technology has been applied in a diverse range of fields spanning flavor ingredient discovery to drug discovery. In a number of these cases, the cell-based discovery systems that had been developed have successfully been employed to discover candidate molecules that work in downstream studies, including in some cases human studies and evaluations for molecules ranging from salt taste enhancers to blockers of pain perception.(8,9)

Looking Towards an Exciting Future

While these data are promising, much work remains to be done. These data demonstrate that for the first time, methods are coming online to access odorant receptors in their native form. This advance by-passes the need to rely on modified receptors, and can be expected to increase the reliability of the discovery platform and the likelihood of success in its use as part of a high-throughput aromatic ingredient discovery engine. Sensory confirmation and perfumery will always be required to identify aromatics that meet desired criteria in sensory applications; however, the ability to rapidly “turbo smell test”

millions of natural ingredients against natural odorant receptors adds a previously unavailable discovery tool.

ABSTRACT

While much of cosmetic chemistry and formulation is directed at maintaining or enhancing the appearance of the external surface of the body, the formulator of products for use in the human mouth must consider a more complex set of issues. Many oral care products address multiple consumer concerns at once, and it is common for an individual product to deliver both drug and cosmetic benefits. Understanding critical elements of oral biochemistry and microbiology will greatly help the formulator design products to deliver these benefits.

In addition to presenting some fundamentals of oral anatomy, physiology, and microbiology, this chapter will focus on the biology behind a variety of oral care consumer needs, the health and cosmetic problems behind these needs, and some approaches to solving these problems that can be introduced into oral care cosmetic or over-the-counter (OTC) drug products. Some of these concerns are summarized in Table 1.

3.6.1 THE TEETH AND THEIR SURROUNDINGS

The oral cavity contains the teeth, tongue, cheeks, palates, and gums (gingival tissues), and is bathed in saliva. The teeth and gums are major sources of consumer concerns, many of them related to dental plaque and other tooth deposits. However, oral care needs arise in other parts of the mouth as well. The following provides an overview of the biology of the oral cavity.

3.6.2 THE TEETH

The normal human dentition consists of 20 primary (“baby”) teeth, which erupt from six months to four years of age, starting with the incisors, and are replaced by 32 secondary (adult) teeth, starting with incisors at about six years of age and culminating with the third molars (“wisdom teeth”), which erupt (in people who have them) around 20–21 years of age. Tooth makeup and form are influenced by genetics, the preeruptive environment (notably nutrition), and the posteruptive environment. Dental anatomy and alignment as well as individual oral care habits and salivary chemistry can have a profound effect upon the quantity, quality, and pathogenicity of the dental deposits that form on the teeth. Different parts of the tooth exhibit markedly different structure and characteristics, which make them prone to different types of problems.

Consumer needs	**Underlying problems**	**Functional solutions**
	“Cosmetic” Indications	
• Attractive teeth/’’ bright smile”	• Dental stain/discoloration • Potentially unsightly dental deposits	• Tooth stain removal/prevention • Plaque/calculus reduction
• Fresh breath	• Intrinsic/ extrinsic oral malodor	• Antimicrobial malodor prevention • Malodor masking/neutralization
• Fresh/clean mouth feeling	• Food/microbial residues (?)	• Flavorants, astringents, remove dental deposits (?)
• Clean mouth • Uncomfortable dental visits	• Dental plaque, calculus, stain • Uncomfortable dental cleaning to remove calculus or stain	• Plaque/calculus reduction • Stain reduction/prevention
• Dry mouth	• Insufficient saliva flow or altered saliva composition	• Lubricating/moisturizing rinses or gels • Artificial salivas
	“Drug” Indications	
• Healthy teeth/strong teeth	• Dental decay	• Decay prevention • Fluorides • Aid salivary function • Remineralization • Saliva stimulation

		• Plaque acid reduction
• Healthy gums	• Gingivitis • Periodontitis (*not* an OTC indication)	• Plaque/gingivitis reduction and prevention
• Sensitive teeth	• Exposed, hypersensitive dentin	• Tooth desensitization
• Oral comfort	• Ulcers of the oral mucosa (e.g., canker sores)	• Topical anesthetics • Antimicrobial agents

Table 1

a. Tooth Anatomy and Structure

Figure 1. Simplified sketch of tooth anatomy The tooth is divided into two areas: the crown (the enamel-covered part of the tooth that extends into the mouth) and the root, which is normally held firmly in place by the bone of the upper and lower jaws (Figure 1). Tooth crowns are covered by dense, hard dental enamel, the hardest tissue in the body. Enamel is thickest at the tip of the tooth and tapers to its thinnest point at the cemento-enamel junction (CEJ), where the crown gives way to the tooth root, which is covered by a thin mineralized layer called cementum. Underlying the enamel and cementum is a less dense mineralized tissue (dentin) that surrounds the dental pulp, which is rich in nerves and blood vessels.

In most individuals, the teeth are closely spaced and often touch side-to-side; the spaces between the teeth are referred to as interproximal spaces. The tooth

roots are held firmly in place in the jaws through periodontal ligaments. In normal healthy teeth, the gums surround the teeth and come to an apex just above the CEJ, so that the roots are not exposed to the oral cavity. The physical shape of teeth varies with tooth type, from the chisel-shaped incisors to the blocky molars, which often have pits and fissures on their biting surfaces. As discussed later, tooth shape can have a profound effect on processes that can lead to various dental problems.

b. Dental Enamel

Dental enamel is composed mainly of a partially carbonated form of the calcium phosphate mineral hydroxyapatite [3Ca3(P04)2.Ca(OH)2], which accounts for about 98% of its composition. Minor amounts of collagen-like protein, remnants of the organic matrix mineralized during tooth development, also remain in the enamel structure. Hydroxyapatite is capable of ion exchange, and anions such as F^- and CO_3^{2-} may replace the $OH^{- -}$ group, while cations such as Zn^{2+}, Sr^{2+}, and Mg^{2+} may replace Ca^{2+}. Caries susceptibility may be influenced by this ion exchange; for example, the extent to which OH has been replaced by F^- has a protective effect on the vulnerability of the enamel to acid demineralization. The hydroxyapatite, of which enamel is largely composed, is present in the form of crystallites that make up rods oriented at right angles to the surface. Water and selected ions can penetrate a small distance into the dental enamel surface along the plane of the crystallites, which can facilitate ion exchange.

As with all calcium phosphate minerals, dental enamel is soluble in acid. A substantial body of data indicates that tooth mineral is highly stable above a pH level of approximately 5.5, referred to as the “critical pH,” and that tooth demineralization occurs when the pH falls below this critical level. The extent of enamel solubility is determined largely by the amount of acid present (measured as pH), the duration of exposure to acid, the amount of soluble calcium and phosphate ions in the fluid bathing the enamel, and the presence of other ions that influence the balance between mineral dissolution and crystallization. Thus the concept of “critical pH,” while useful, should not be considered to be an absolute value.

c. Dentin

The layer of material beneath tooth enamel and cementum is the dentin. It contains approximately 70% hydroxyapatite, with the balance of its composition being collagen. Unlike the structure of enamel, which is characterized by

densely packed crystals, the dentinal matrix is perforated by a number of tiny, fluid-filled canals (dentinal tubules) that radiate from the pulp cavity to the surface. Dentin can be exposed to the oral cavity through damage to the enamel or gingival recession and wearing of the cementum (the mineral layer covering the dentin of the tooth root). The presence of open dentinal tubules can lead to hypersensitivity, in which the exposed dentin may be painfully sensitive to various stimuli, including heat, cold, pressure, sugar, acid, and so forth. This is discussed in more detail later in this chapter.

Dentin, like enamel, is also acid-soluble. Because it has less mineral content, and possibly because its structure more readily permits penetration of bacteria and acid, exposed dentin is generally believed to be more susceptible to decay than enamel. This explains the rapid advancement of dental decay after it penetrates the enamel layer and the vulnerability of exposed tooth roots to decay.

3.6.3 THE GUMS

The gums (gingival tissue) surround the teeth and overlie the bony structure in which the teeth are anchored. In health, the gum tissues directly adjacent to the teeth (the gingival margin) are firm and pink, extend just above the CEJ, and form a crevice that is not more than 3 mm deep. If dental plaque is permitted to accumulate adjacent to the gingival margin and within the gingival crevice, the gum tissue can become irritated, inflamed, and liable to bleeding. In some cases this inflammatory state stabilizes as chronic gingivitis, while in other cases the inflammation can advance to the destructive disease periodontitis.

3.6.4 ORAL FLUIDS

a. Saliva

Saliva is a major factor in the maintenance of a healthy mouth. Saliva is continuously being produced, bathing teeth and oral tissues in a dynamic environment that serves to lubricate the mouth, remove harmful materials from the oral environment, and maintain the mineral balance of the teeth.

Saliva is produced by three pairs of major glands and the smaller glands of the oral mucosa (labial, lingual, buccal, and palatal). The secretions differ from one another in composition and may also differ according to the rate of flow, time of

day, and so forth. For instance, it is well known that salivary flow is reduced at night; this makes it extremely important to cleanse the teeth between that previous midnight snack and going to bed, as the protective effects of saliva are substantially reduced during sleep.

Saliva contains mucopolysaccharides, proteins, enzymes, and inorganic materials such as calcium, sodium, potassium, chloride, bicarbonate, and phosphate ions, and bacteria shed from the oral surfaces and a variety of their constituents. The organic constituents of saliva are thought to be responsible for the development of the acquired dental pellicle (as described later). The presence of calcium and phosphate ions and the bicarbonate buffer system are believed to be significant both in the control of dental caries and in calculus formation. The pH of resting saliva ranges from about 6.5–7.2, while that of stimulated saliva can range up to about 8.0; the pH increase reflects a higher bicarbonate content in simulated supply.

The importance of saliva in preventing tooth decay following eating was demonstrated in the 1940s by R.M. Stephan. He devised a miniature pH electrode from antimony and used it to determine the pH of dental plaque at various sites on the teeth. His experiments showed that the pH of dental plaque decreased rapidly from about pH 6.82 to about pH 5 within a few minutes after consuming a sugar challenge and slowly returned toward neutrality over the next 20 to 60 minutes. If saliva flow to the teeth was restricted, the pH would remain depressed below the critical pH for enamel demineralization for much longer periods. The importance of saliva in maintaining oral pH may partially explain why an inadequate flow of saliva resulting from head and neck irradiation, drug-induced hyposalivation, or pathology can result in increased caries susceptibility and other oral problems.

b. Gingival Crevicular Fluid (GCF)

GCF exudes from the epithelium within the gingival sulcus or pocket. It is more similar to blood plasma than to saliva and can serve as a source of nutrients to the bacteria growing within the sulcus and along the gingival margin; it can also carry a variety of specific and nonspecific host defense factors.

3.6.5 THE ORAL SOFT TISSUES

The oral soft tissues consist of the tongue, gums, cheeks, hard and soft palate,

and sublingual region. The oral soft tissues are covered by a variety of nonkeratinized and keratinized epithelia. The surface of the soft tissues, most notably the tongue, can harbor large populations of oral bacteria that can serve as a reservoir to recolonize the teeth after cleaning. The microbial flora of the tongue can also play a prominent role in the generation of oral malodor (bad breath). Additionally, certain oral soft tissues are prone in some individuals to develop painful sores or ulcers, for example, aphthous ulcers (canker sores), which are addressed at greater depth later in this chapter.

3.6.6 DENTAL DEPOSITS

As soon as a tooth erupts into the mouth, and subsequently after every cleaning, it is prone to coverage with a variety of dental deposits that can cause diverse conditions that concern consumers. The enamel of a freshly cleaned tooth is rapidly covered by a pellicle of proteins adsorbed from saliva, followed by salivary bacteria that form dental plaque. Dental plaque bacteria can, under certain conditions, release by-products that can be harmful to the teeth or gums. Dental pellicle and plaque are also liable to accumulation of stain and neutralized deposits (dental calculus or tartar).

a. Dental Pellicle

Immediately after cleaning, the enamel surface is covered very rapidly by a 1–3 µm thick film of proline-rich phosphoproteins, peptides, and glycoproteins adsorbed from the saliva; thus the presence of a truly “clean” enamel surface in the oral environment is a fleeting phenomenon. The adsorption of salivary peptides and proteins appears to be relatively specific, starting within minutes of a tooth cleaning and continuing for several hours. While the acquired enamel pellicle is free from bacteria, it has been shown to contain a variety of bacterial constituents including enzymes such as glucosyltransferase, soluble polysaccharides, and various bacterial cell wall constituents.

b. Dental Plaque

Dental plaque has been recognized for centuries as a sticky film that forms on the teeth and has been the subject of concern as far back as the ancient Greeks. Over the years, the composition of dental plaque was thought to consist of food debris, mucus, denatured saliva, or “evil humors.” It was Anthony van

Leeuwenhoek, the inventor of the microscope, who first observed “tiny animalcules” (bacteria) in dental plaque in 1677. Around 1895, W.D. Miller established quite convincingly that dental plaque contained bacteria that could form acids from foods and that the acids could dissolve tooth enamel. This chemoparasitic theory of dental disease evolved to the belief that the way to control dental disease was to eliminate dental plaque, if not all bacteria, from the mouth. However, it was not until the 1960s through the 1980s that oral microbiologists started to understand the complexity and sequence of dental plaque and how it contributes to oral health and disease. Understanding the ecology of dental plaque and its effect on the character and pathogenicity of the plaque flora can provide strong insight into how a healthy balance with our natural oral flora can be established.

A central concept in our understanding of dental plaque and its pathogenicity is that plaque is actually a complex and heterogeneous microbial biofilm that varies substantially from site to site within the mouth, changes in nature over time, and is sensitive to a number of ecological parameters that can affect both its quantity and its quality. Dental plaque grows in an ordered manner, starting with the attachment of certain classes of bacteria (Gram-positive cocci) to the salivary pellicle through a set of relatively specific binding reactions similar to the interaction of antigens and antibodies. In general, these early colonizers are not associated with dental disease. Further plaque accumulation is a process combining growth of the early colonizers, elaboration of a sticky extracellular matrix that helps the bacteria adhere to the teeth and each other, and attachment and proliferation of additional bacterial species. Just as a plowed field can over time undergo succession from bare soil to grasses and weeds to shrubs to various species of trees, culminating in a mature forest, dental plaque changes and becomes more complex over time, dental plaque changes and becomes more complex over time. While the initial colonizing bacteria on smooth tooth surfaces are generally tolerant of oxygen and relatively nonpathogenic, later colonizers (especially in the region along the gumline and between the teeth where plaque tends to be thickest) become much richer in oxygen-intolerant anaerobic bacteria that can be associated with gum disease. In contrast, the microbial flora of tooth sites with reduced access to saliva (e.g., in the pits and fissures of the molars or in the interproximal spaces where teeth are tightly pressed together) can become dominated by bacteria that are relatively resistant to acid and can continue to produce acid at levels that can lead to tooth decay. The importance of particular populations of oral bacteria to oral problems such

as dental decay, gum disease, and oral malodor will be discussed in more detail later.

For further reading on dental plaque formation and ecology, its relation to disease, and strategies for controlling its pathogenicity, see the reviews by Burne and by Marsh *et al.* [1, 2].

c. Dental Calculus

The term "tartar" was commonly used to describe the mineralized deposits formed on neglected teeth. The origin of the term was derived from the similarity of mineralized dental deposits to the crystalline deposits formed in wine. The most common term in use is *calculus*. It may occur both above (supragingival) and below (subgingival) the gumline. Although these two forms of calculus may differ somewhat in composition, they both appear to originate from the mineralization of dental plaque bacteria and extracellular matrix.

Dental calculus varies in composition but always consists of about 80% of inorganic material containing calcium, magnesium, phosphorus, and other elements. The calcium and phosphorus are present in early plaque as Brushite ($CaHPO_4 \cdot 2H_2O$) and octacalcium phosphate [$Ca_8(HPO_4)_2(PO_4)_4$]. Whitlockite [$Ca_3(PO_4)_2$] may also be found, but the ultimate stage is probably apatite [$3Ca_3(PO_4)_2 \cdot Ca(OH)_2$]. This transition, which is also characterized by increasing mineral hardness and tenacity, is helped by the presence of fluorine, which is present in calculus to the extent of about 400 ppm. The remaining 20% of calculus is an organic matrix containing carbohydrate, protein, lipid, and bacteria and their constituents.

Calculus is first observed when the plaque on the enamel surface begins to mineralize. Today the most generally accepted explanation is that calculus is formed by a seeding mechanism, followed by calcium phosphate crystal growth and maturation. Rates and amounts of calculus formation can vary widely among people and within the mouth. This is probably due to a variety of factors, including salivary chemistry, local pH, plaque accumulation, and oral hygiene.

3.6.7 MAJOR ORAL PROBLEMS AND THEIR REMEDIES OVERVIEW

The major oral care problems that concern consumers can be broadly categorized as medical or cosmetic, although some conditions may fall within

both categories. Medical concerns for oral health include dental decay and gum disease (both associated with distinct pathogenic dental plaque floras), dental hypersensitivity, and dry mouth. Cosmetic concerns include dental staining and tooth whitening, oral malodor, and dental calculus. Some of these problems are widely distributed in the population worldwide, while others are less common.

a. Dental Plaque

Dental plaque is not actually a problem, as it is ubiquitous in individuals exhibiting both dental health and dental disease. However, as discussed earlier, certain populations of microorganisms in dental plaque exhibit characteristics that play a major role in the causation of dental decay and gum disease. It is important to remember that the pathogenicity of dental plaque is related not only to its mass but also to relatively specific classes of microorganisms. For instance, individuals with active dental decay tend to harbor higher populations of plaque bacteria that can produce and tolerate higher levels of acids, which are responsible for the destruction of tooth enamel. In contrast, dental plaque associated with gum disease tends to be highly populated with anaerobic Gram-negative bacteria that produce toxic substances such as volatile sulfur compounds, short-chain fatty acids, or bacterial toxins. These substances may directly damage or irritate gum tissues or might cause an inflammatory response that can lead to pathological changes in the gum tissue. In many cases the microbiological character and pathogenicity of dental plaque can be markedly modified by behaviors, such as oral hygiene or dietary habits, which can have a profound influence on plaque ecology and the rise or control of pathogenic microbial communities in the plaque.

A wide variety of methods are used to study dental plaque in the oral cavity. Some clinical indices are used to record quantity of plaque on individual tooth surfaces whilst others are used to characterise plaque accumulation on different regions of the tooth such as on the gum margin or between the teeth. This variety of methods reflects the range of claims made for oral care products. For example, a toothbrush study may want to demonstrate superior cleaning on the gum margin or between the teeth, while an antiplaque toothpaste might demonstrate reductions in overall plaque accumulation on the tooth.

b. Dental Calculus

It has been recognized for some time that there is an association between the presence of calculus and the incidence of periodontal disease, although

enthusiasm for this concept waned considerably in the middle part of the twentieth century. The commonly accepted theory is that calculus irritates the gingival tissues and encourages the formation of a pocket between tooth and gingivae, in which food debris and bacteria may lodge. However, dental calculus is considered a cosmetic issue. Even in the absence of concern regarding pathogenicity, consumers have reason to care about controlling calculus. Its accumulation can be unsightly, and it is a frequent cause for uncomfortable visits to the dentist that are required for its removal from the teeth.

While mechanical treatment by a dental professional is the only means of removing calculus, it is possible to prevent or slow its formation by a number of physical and chemical means. Mechanical plaque control (i.e., brushing and flossing) can be very effective in reducing calculus formation by removing the plaque matrix required to initiate calculus calcification. For those individuals who require additional assistance in calculus control, there are a variety of oral care products, primarily toothpastes, that contain agents that inhibit calcium phosphate crystal growth and thereby calculus formation. The most common agents in tartar control toothpastes are pyrophosphate and zinc salts such as zinc citrate, although there are a variety of other calculus-inhibiting compounds in products and in the patent literature. At present there is one tartar control mouthrinse on the market, which uses zinc chloride as the antitartar agent. The current mechanism of action of anticalculus agents is thought to lie in their ability to interfere with the initiation or maturation of calcium phosphate crystals, resulting in less mineral mass and a less mature mineral structure that is softer and more easily removed by mechanical scaling. For further reading on dental calculus formation and control, see the reviews by Ciancio [3], Mandel [4], and Jepsen *et al.* [5].

c. Dental Caries (Tooth Decay)

Dental caries, commonly known as tooth decay, is a disease that is widely distributed worldwide and is associated with more frequent consumption of foods containing sugars or refined starches. Tooth decay used to be considered a disease of children, especially in affluent societies with plentiful access to sugary foods, since most tooth surfaces became decayed by early adulthood. In recent years, preventive measures such as water fluoridation, the use of fluoride toothpastes, and the placement of occlusal sealants has resulted in very significant reductions of childhood caries. While these reductions in tooth decay may carry over into adulthood, an intact tooth surface is at risk throughout the

life of an individual, and adults must also pay attention to caries prevention.

Dental decay occurs as the results of tooth demineralization by acids produced during carbohydrate fermentation by dental plaque bacteria. It is interesting to note that consumption of carbohydrates always results in the production of plaque acids but does not always result in tooth decay. This is because saliva can often neutralize and wash away plaque acids and deliver calcium and phosphate salts to remineralize enamel before irreversible damage is done to the tooth structure. Tooth decay occurs only if the magnitude and frequency of carbohydrate consumption cause decreases in plaque pH of magnitude and duration sufficient to overcome the natural reparative power of saliva.

Enamel decay usually starts in small circumscribed areas and spreads beneath the intact tooth surface. Early carious lesions, frequently referred to as “white spot” lesions, are characterized by a thin layer of intact dental enamel overlying partially demineralized dental enamel. A critical feature of these incipient lesions is that under the right conditions they may be reversed or arrested by the process of remineralization. This process is significantly enhanced by the presence of fluoride and extra calcium and phosphate ions in saliva and plaque fluid.

If the acid challenge is great enough in both magnitude and duration, the demineralization penetrates deeper into the enamel and spreads within it, roughly assuming the shape of a cone with its apex orientated toward the dentino-enamel border and the base still below the enamel surface. The lesions may still be reversed by conscientious use of fluoride or other remineralizing strategies. At this stage of the process there still may be no visible break or cavitation evident on the enamel surface. It is generally accepted that the dentin begins to demineralize or soften before an actual cavity becomes visible. Gradually the tissue softens sufficiently so that it breaks. At this point, the carious lesion becomes a cavity and can no longer be repaired by natural means, requiring restoration by a dentist.

Control of Caries

Reduction of Fermentable Carbohydrate Intake and Removal of Fermentable Debris from the Mouth A very large body of clinical and experimental evidence implicates the consumption of fermentable carbohydrates, especially sucrose, as a major causative factor in tooth decay. Reducing the consumption of fermentable carbohydrates, most especially reducing the frequency of intake, can markedly lower caries risk. A major cause of this reduction is almost certainly a decrease in the magnitude and duration of acid formation by dental plaque,

permitting more effective remineralization by saliva. Any action that accelerates removal of fermentable food residue from the mouth, such as rinsing and brushing of the teeth, can also shorten the duration of acid attack. Furthermore, a substantial number of studies indicate that stimulation of salivary flow by chewing a nonacidogenic substance such as sugarless gum can also accelerate the removal of fermentable residue and increase the rate of salivary buffering in the mouth. For further reading on the impact of diet and eating patterns on dental caries, see the review by Geddes [6].

Reduction in Bacterial Activity and Plaque Pathogenicity Bacteria present in the mouths of most individuals will ferment carbohydrates, especially sugars, causing a pH drop to levels ranging from about 5.5 to under 4.5, below the critical pH for enamel demineralization. This fall in pH is represented by the classic Stephan curve, which can be reproduced *in vitro* and *in vivo*. Certain microorganisms, including *Lactobacillus acidophilus* and *Streptococcus mutans*, have been identified as specific caries-causative pathogens. These microbes are particularly effective at producing acid and are particularly resistant to acid environments, which can lead to their domination in pre-carious and carious dental lesions. Thus practices that reduce the amount and duration of plaque acid production, such as less frequent snacking, may also produce reductions in these particularly cariogenic plaque bacteria. There is also evidence suggesting that some substances such as fluoride, chlorhexidine, or the sugar substitute xylitol may inhibit the metabolism of cariogenic plaque bacteria.

Tooth decay tends to occur more frequently on regions of the tooth that have relatively restricted access to saliva (e.g., in the pits and fissures on the tops of the teeth, or between the teeth) or on areas of exposed dentin, such as exposed tooth roots, which are more acid-soluble than tooth enamel. Thus measures that decrease bacterial access or accumulation to these restricted areas, such as placing occlusal sealants or flossing between the teeth, can substantially reduce their susceptibility to dental decay. There is also some evidence that placing occlusal sealants not only reduces caries but also may help reduce overall risk of dental caries by eliminating sites that are the primary ecological niches for S. mutans and other acid-tolerant, potentially cariogenic bacteria.

Decrease of Susceptibility of Tooth to Acid Attack It is clear that fluoride ions decrease the acid solubility of hydroxyapatite; the two strongest hypotheses for this protective effect are that fluoride may ion-exchange with the hydroxyl group in hydroxyapatite to produce more resistant fluorapatite, and fluoride ions present during acid challenge may decrease solubility at the enamel surface. This

effect on enamel solubility may be a principal mechanism by which water fluoridation and fluoride-containing toothpastes and mouthwashes exert their effect. In 1952, it was established in the United States that there was an inverse relationship between the incidence of caries in children and the fluoride content of the local water supply, and subsequent clinical and public health studies have firmly established the value of water fluoridation as a safe and effective way of reducing dental decay.

In the 1950s, fluoride toothpastes were introduced in the United States and are now available worldwide. A substantial body of experimental and clinical data clearly supports the highly significant clinical value of fluoride dentifrices and mouthrinses in the prevention of dental decay. The most common sources of fluorides used in oral care products are sodium fluoride, stannous fluoride, monofluorophosphate, and amine fluoride (amine fluoride is not approved for use in the United States). Anticaries fluoride products are regulated as drugs; in the United States, requirements for active ingredients, specifications, and testing of anticaries drug products for OTC human use are detailed in a final monograph (21 CFR Parts 310, 355, and 369, and Docket No. 80N-0042).

Remineralization

An additional approach to reducing dental decay is promoting the remineralization of dental enamel. As stated earlier, dental plaque acids act to dissolve dental enamel, and this is counterbalanced by the remineralizing action of saliva. Increasing the oral concentration of ions that enhance this reparative process may substantially reduce dental decay. Fluoride is well known to increase the rate of remineralization and the resistance of dental enamel to subsequent acid attack. A growing body of work suggests that increasing levels of available calcium may also increase the rate of remineralization. Approaches to increasing orally available calcium include methods as diverse as using two-phase systems to promote the deposition of calcium fluoride on the tooth surface and the use of calcium-and phosphate-rich milk proteins to speed remineralization. Currently additional remineralizing strategies to reduce dental caries are still under development. One issue that is still unclear is the potential effect of aggressive remineralizing strategies on the rate of dental calculus formation, which would be an undesired side effect. For additional reading on dental caries prevention, see the reviews by Featherstone [7], Edgar *et al.* [8], and Pitts [9].

In clinical studies of anticaries products the number of Decayed (D), Missing

(M) or Filled (F) teeth (T) or surfaces (S) occurring during a clinical trial are compared using the DMFT or DMFS indices, representing the sum of the Decayed, Missing, and Filled surfaces or teeth. Uppercase letters are used to designate the permanent dentition and lowercase the primary dentition. Historically these indices have been used to measure dental caries when they reach the stage of dentine involvement (cavitation), and such studies often involve many thousands of subjects over two or three years. More recently there has been a move to methods that consider remineralization and demineralization of early caries lesions (white spots). New caries classification systems such as those proposed by the International Caries Detection and Assessment (ICDAS) group [Pitts, 9] have been developed to assist in this process. There has also been a wide range of detection methods developed that enable monitoring of lesions such as those using Quantitative Light Induced Fluorescence (QLF, Inspektor, Amsterdam, Netherlands), Electrical impedance (CarieScan, Dundee, Scotland), and Red Fluorescence (Diagnodent, Kavo, Biberach, Germany).

d. Dental Erosion

Dental erosion is the dissolution of enamel and dentine by acid of either intrinsic or external origin. It is distinguished from dental caries in that the acid does not originate from fermentation of sugars by bacteria in dental plaque. The rate and severity of dental erosion is a result of the interplay between several chemical, biological, and behavioral factors. The various chemical properties of the acid like its pH, titratable acidity or buffering capacity and calcium-chelation ability determine its erosive potential. Biological factors like the various characteristics of saliva and acquired pellicle have also been found to be important in the development of dental erosion. The acquired pellicle may protect against erosion by acting as a diffusion barrier or a perm-selective membrane preventing direct contact between the acids and the tooth surface. Behavioral factors like the frequency and timing of consuming acidic beverages and food and abnormal eating and drinking habits have also been attributed to the development of dental erosion. Swishing of the erosive agent in the mouth increases agitation of the erosive agent and hence enhances the dissolution process because the solution on the surface of the hard tissue is readily renewed.

In the mouth the erosive process is complicated by mechanical forces from abrasion and attrition of the vulnerable softened layer.

e. Periodontal Diseases (Gingivitis and Periodontitis)

Teeth are attached to the basal bones of the jaw through the periodontal tissues and are surrounded by gingival tissues. In health, the gingival tissues are firm and the gingival crevices are relatively shallow. However, the gingival and periodontal tissues are susceptible to a variety of inflammatory diseases, generally classified as periodontal diseases. The most common of these are gingivitis and periodontitis.

Gingivitis is a reversible inflammation of the gums that is not accompanied by irreversible destruction of the periodontal support tissues. Gingivitis is associated with increased dental plaque accumulation and/or high populations of Gram-negative anaerobic bacteria in the plaque and is characterized by inflamed and easily bleeding gums. Gingivitis appears to be caused by substances produced in plaque that irritate the gum tissues and induce inflammation. There is a considerable body of evidence suggesting that, while gingivitis is not associated with a single pathogenic species, different groups of organisms are clearly associated with higher or lower capacity to promote gingivitis. Dental plaques dominated by species associated with early plaque colonization (e.g., Gram-positive streptococci) are more highly associated with gingival health, while more mature dental plaques dominated by Gram-negative anaerobic species such as *Fusobacterium nucleatum* and *Prevotella intermedia* are more highly associated with gingivitis. These Gram-negative species produce a variety of toxic or irritating substances including volatile organic acids (e.g., butyric or propionic acid), volatile sulfur compounds (e.g., H_2S or methyl mercaptan), various antigens, and endotoxins. These irritating substances are hypothesized to penetrate the gingival epithelium and provoke the body's inflammatory defense systems, which ultimately leads to the swollen and bleeding gums characteristic of gingivitis.

Gingivitis prevention has focused on mechanical and chemotherapeutic measures that reduce plaque mass and inhibit the emergence of more pathogenic microbial species. Many clinical studies have demonstrated that gingivitis can be reduced or eliminated by improved mechanical oral hygiene (i.e., better brushing and flossing), which reduces the amount of dental plaque and also selects for a less pathogenic, Gram-positive dominated plaque flora. As adjuncts to mechanical oral hygiene, a number of oral hygiene products containing antimicrobial agents have been formulated to help prevent gingivitis by chemical means. These compositions apparently exert their therapeutic activity by killing and inhibiting the growth and metabolism of plaque bacteria (thereby reducing plaque mass), slowing the progression of the plaque microflora toward

enrichment for more pathogenic Gram-negative anaerobes, and reducing the production of microbial irritants. Agents that have been clinically demonstrated to reduce gingivitis include chlorhexidine, a fixed ratio of essential oils (thymol, menthol, methyl salicylate, and eucalyptol), triclosan, stannous fluoride, and cetylpyridinium chloride. In 1998, the United States Food and Drug Administration concluded panel hearings on antiplaque, antigingivitis drug compositions. The panel voted and published in 2003 a recommendation to accept some of these agents as antiplaque, antigingivitis agents.

A number of other chemical interventions for plaque and gingivitis control have been proposed, although these technologies are not yet available. These approaches include measures to prevent colonization or aggregation of one or more species of plaque bacteria, measures to disaggregate plaque to make it easier to remove, and measures to reduce the host inflammatory response.

Periodontitis is a more serious form of periodontal disease characterized by severe inflammation, increased pocket depth, and irreversible loss of alveolar bone supporting the teeth. Current thinking about the etiology of periodontitis suggests that it results from an interaction between certain classes of particularly pathogenic microorganisms and the patient's specific and nonspecific inflammatory defense mechanisms. The pathogenic bacterial species associated with gingivitis and periodontitis overlap to some extent, although periodontitis-associated dental plaques contain some particularly pathogenic species such as *Porphyromonas gingivalis* and *Bacteroides forsythus*, which are not generally associated with gingivitis. Periodontitis is frequently preceded by and accompanied by gingivitis, but not all dental sites with gingivitis will progress to periodontitis. Periodontitis appears to progress in an episodic fashion characterized by short periods of rapid bone loss (possibly caused by a severe acute inflammatory episode) followed by extended periods of chronic inflammation and relative clinical stability. Periodontitis can only be diagnosed and treated by dental professionals, and there are no OTC oral care products specifically directed to reduction or prevention of periodontitis. However, prescription and OTC products clinically proven to reduce plaque and gingivitis are often included in supportive oral hygiene regimens after periodontal treatment. For further reading on the pathogenesis and treatment of gingivitis and periodontitis, see the reviews by Ciancio [3].

f. Dentinal Hypersensitivity

In healthy teeth the dentin of the crown and tooth root is generally covered

completely by enamel or gum tissue. However, when dentin is exposed by enamel decay or fracture or gingival recession that exposes the tooth root, it becomes susceptible to a variety of problems. Gingival recession can occur for a variety of reasons, including periodontal disease, gingival injury from improper brushing of the teeth, and so forth. Once exposed, the cementum covering the root can be quickly worn away to expose the dentin. In a substantial number of individuals, exposure of dentin can lead to sensitive teeth (dentinal hypersensitivity), in which a variety of stimuli (e.g., heat or cold, pressure, or high-sugar foods) can trigger discomfort ranging from a mild twinge to severe pain. It is estimated that one in seven people is affected by some degree of dentinal hypersensitivity. In its more severe forms this condition can be debilitating, affecting the dietary and oral hygiene habits of the patient.

While several theories have been advanced to explain the mechanism of dentinal hypersensitivity, the most accepted model is the hydrodynamic theory. This theory proposes that exposed, unblocked dentinal tubules provide a channel from the outer surface of the tooth to the nerves in the pulp. Physical and chemical stimuli are postulated to affect the pressure on the fluid within the dental tubules, and these changes in hydrodynamic pressure are transmitted to the pulp nerves and interpreted as pain signals. The elements of the hydrodynamic theory (i.e., open dentinal tubules and responsive pulpal nerves) suggest two possible approaches to the reduction of dentinal hypersensitivity: blocking the tubules or reducing the stimulation of pulpal nerves.

There are a variety of currently available professional and self-applied treatments for dentinal hypersensitivity. The OTC products are dentifrices that provide agents that either promote blockage of open dentinal tubules (e.g., strontium chloride, arginine—calcium carbonate or stannous fluoride) or reduce the sensitivity of pulpal nerves by depolarizing the nerve membranes (e.g., potassium nitrate, potassium chloride, or potassium citrate).

For further reading on the origin and treatment of dentinal hypersensitivity, see the reviews by West *et al.* [11] and Ciancio [3].

g. Dental Staining

While it does not contribute to dental disease, dental staining is of considerable concern to a large number of consumers who believe that stained teeth detract from their overall appearance. This concern is possibly most acute in the United States, although there is evidence that the desire for “cleaner, brighter” teeth is increasing in other parts of the world. Dental stain or discoloration can be

roughly categorized as either intrinsic or extrinsic. Intrinsic discoloration exists within the tooth structure itself and may result from discoloration laid down during tooth formation, thinning of tooth enamel (permitting the color of the underlying dentin to show through), or loss of tooth vitality. Extrinsic discoloration results from deposition of exogenous colored material (chromogens) on the tooth surface. There are a variety of theories concerning the chemistry of extrinsic tooth staining, which probably results from a number of causes. These may include binding of ingested chromogens (e.g., pigments from tea, coffee, or tobacco) to the tooth surface either directly or through mediation of “bridging” molecules, binding of metal ions such as tin or iron (which can form a variety of pigmented complexes) to the tooth surface, or the binding to the tooth surface of colorless substances that later undergo a chemical reaction that transforms them to colored compounds. For further reading on the chemistry and mechanisms of dental staining, see the review by Nathoo [12].

There are a variety of measures to reduce or prevent dental staining, which can be grouped into measures that remove extrinsic stain by mechanical or chemical means, measures that prevent extrinsic stain buildup, and measures that chemically bleach extrinsic or intrinsic dental stain. Consumer products that mechanically remove dental stains are probably the most abundant and are dominated by dentifrices containing a variety of abrasive systems. Some of these products, most notably some targeted to smokers, are more abrasive than “normal” toothpastes; care must be taken while formulating or selecting these products that a safe range of abrasivity is not exceeded. There are also a number of OTC dentifrices or mouthrinses that claim to bind to complex staining compounds and prevent their accumulation.

There are a growing number of professional and self-applied products that contain bleaching agents that can reduce the color of extrinsic or intrinsic dental stain. Bleaching products contain a variety of peroxides (e.g., hydrogen peroxide, carbamide peroxide) and chlorine compounds (e.g., chlorine dioxide), and exhibit a range of clinical effectiveness. Because it is possible that some of these bleaching agents could be harmful to the teeth or oral soft tissues, especially if misused, this class of products has come under increasing scrutiny from regulatory and professional agencies. For instance, oral care products containing peroxide are not permitted in Canada. While it is possible to make a variety of safe and effective bleaching products to reduce dental staining, the formulator is well advised to become familiar with applicable standards and regulations to ensure product safety and regulatory compliance.

h. Oral Malodor

Another concern of consumers of cosmetic oral care products is oral malodor (also known as bad breath or halitosis). Bad breath has been of documented concern since ancient Greek and Roman times and continues to be of concern. Oral malodor can be classified into two basic categories, intrinsic and extrinsic. Intrinsic oral malodor has its origin within the individual and is most commonly caused by substances produced by bacteria in the oral cavity. Malodorous substances of bacterial origin are primarily produced by anaerobic species (some, but not all, of which may be associated with gingivitis or periodontitis) and include volatile sulfur compounds, volatile organic acids, and a variety of other volatile malodorous compounds. A smaller, but still significant, source of intrinsic oral malodor is a variety of systemic diseases or disorders that result in the exhalation of malodorous substances in lung air.

Extrinsic oral malodor originates from the ingestion of substances (such as garlic, cheese, tobacco, etc.) that contain malodorous compounds. The duration of extrinsic oral malodor is proportional to the amount and frequency of ingestion of the offending substance and the amount of time required to “wash out” the malodorous substances.

While there is relatively little that can be done to alleviate intrinsic oral malodor arising from systemic disease or disorder short of correcting the underlying condition, there are many approaches and products directed at reducing extrinsic and intrinsic malodor of oral origin. These approaches can be categorized into those that remove or wash away the malodorous substances, those that mask or cover up malodorous substances with more pleasant-smelling flavors or fragrances, those that chemically bind and neutralize the malodorous substances, and those that prevent or reduce the elaboration of intrinsic oral malodors.

Mechanical means of removing oral malodor include rinsing the mouth and brushing or scraping the teeth and tongue. In addition to washing away malodorous substances, improved oral hygiene can affect the ecology of the microbial communities in dental plaque and on the tongue, reducing the populations of anaerobic bacteria that are responsible for a large portion of intrinsic oral malodor and for gingivitis and other oral diseases.

Numerous products are employed to cover up bad breath; these include a variety of cosmetic mouthrinses, toothpastes, mints, chewing gums, and breath sprays whose principal function is to introduce flavors (such as mint) that can

overpower or mask unpleasant mouth odors. Note that many of these approaches also increase the wash-out of odorous substances either directly (e.g., mouthrinses) or indirectly through salivary stimulation (e.g., chewing gums or breath mints). For these products, a formulator's concern is primarily directed at improving the delivery and residence time of the "reodorant" flavor systems.

Another very popular approach to reducing oral malodor is to interfere with the ability of oral bacteria to produce malodorous substances. The most common means of achieving this is through the use of products containing antimicrobial systems that either kill or metabolically inhibit substantial populations of bacteria that produce the offending substances. Since bacteria that are dead or injured are incapable or less capable of metabolizing and producing malodorous substances, this approach can be highly effective in reducing malodor originating from bacteria growing in dental plaques or on the tongue. Many of the antibacterial products used to reduce plaque and gingivitis (e.g., a mixture of four essential oils, chlorhexidine, triclosan, or stannous fluoride) may also be useful in controlling intrinsic oral malodor.

A fourth approach to controling oral malodor is to ingest materials capable of binding with volatile odorous compounds and either neutralizing them or rendering them nonvolatile. Examples of products embodying this approach include those that contain metal ions such as copper, zinc, or tin (i.e., stannous ion), all well known to bind with volatile sulfur compounds. Other products in this class contain baking soda, which is also claimed to neutralize a variety of volatile malodorous compounds. These anti-odor substances have been formulated into mouthrinses, toothpastes, chewing gums, mints, and other oral dosage forms. Another class of compounds that has been proposed to systemically inactivate malodor consists of herbs or herb extracts (such as parsley oil) that are consumed as powders, tablets, or capsules. These products, which claim to inactivate malodorous substances in the stomach and thereby lower oral malodor, have not been demonstrated to have any value in reducing oral malodor. For further reading on the causes and management of oral malodor, see the review by Scully *et al.* [13].

i. Dry Mouth (Xerostomia)

Reduced saliva flow leading to dry mouth syndrome (xerostomia) can originate from a number of sources, including systemic disease, destruction of salivary gland tissue by radiation or chemotherapeutic cancer treatment, and medicinal drug use. While systemic diseases (such as Sjogren's syndrome) that destroy

salivary function are relatively rare, induced dry mouth syndrome, especially that caused by drug use, occurs to some extent in a substantial percentage of the population. Total or near total destruction of salivary function such as that exhibited by patients with Sjogren's syndrome or head and neck irradiation for cancer treatment can have a devastating effect on the oral cavity. Rampant caries, severe fungal infections such as candidiasis (thrush), loss of ability to taste, discomfort due to a pronounced sense of dryness, and irritation of the oral soft tissues are common in patients affected by severe xerostomia. Dry mouth of lesser severity, for instance that caused by some drugs, can also result in some of these problems, although usually to a less severe degree. There are now over 200 prescription and nonprescription drugs known to reduce saliva flow, including antidepressants, antihypertensives, and antihistamines; therefore this is more than a minor problem, especially in older individuals taking multiple medications.

Management of patients with dry mouth generally involves first reducing their susceptibility to oral disease. This commonly includes daily use of fluoride mouthrinses or gels and the use of antifungal drugs when necessary. A number of other products generally classified as "artificial salivas" are also available to increase the patients' comfort by reducing the sensation of oral dryness. These products typically contain a variety of humectants and lubricants to increase the sensation of oral moistness, as well as buffers and sometimes fluoride.

For further reading on xerostomia evaluation and management, see the review by Eveson [14].

j. Aphthous Ulcers (Canker Sores)

While oral ulcers, most notably canker sores (aphthous ulcers), are not as widely distributed a problem as gingivitis, they still affect millions of patients yearly and can be very troublesome and painful to those unfortunate enough to suffer them. Canker sores most commonly arise on the tongue and buccal mucosa. Their cause is still a matter of some debate and has been variously attributed to bacterial, viral, and autoimmune factors, although the evidence for an autoimmune origin is currently the strongest. A variety of factors has been suggested to predispose susceptible individuals to a canker sore attack, including minor injuries or irritation to the tongue or oral mucosa, selected foods, sodium lauryl sulfate (in toothpaste), and the like. Canker sores are characterized by shallow crater-like lesions approximately 2–10 mm in diameter (although sometimes larger) with sunken, grayish centers and slightly raised borders. They

can occur singly or in multiple clusters. Once manifested, they last approximately five to ten days and can be quite painful. For review see Akintoye [15].

There is no known prevention for canker sores except to avoid things that the patient's experience suggest are predisposing factors. Treatment of existing canker sores is generally targeted at reducing discomfort or speeding healing. Several products aimed at reducing discomfort contain topical anesthetics such as benzocaine or lidocaine, while others include agents such as diphenhydramine or corticosteroids to reduce the inflammatory response. Antimicrobial mouthrinses, most notably mouthrinses containing essential oils or chlorhexidine, have been shown to speed healing or reduce the incidence of canker sores. Agents such as silver nitrate or sulfuric acid have also been suggested to cauterize canker sores; this approach is generally regarded as unsafe and not recommended. As additional information regarding aphthous ulcers becomes available, additional approaches to treatment and prevention can be expected.

SUBSTRATE:
THE LIPS

LIP SKIN: STRUCTURE AND FUNCTION

Author

Philip Wertz, Ph.D.

Dows Institute
University of Iowa
Iowa City IA 52242 USA

ABSTRACT

The lips are covered by a thin keratinized epithelium layer on a flexible, connective tissue with a rich blood supply. The *stratum corneum* on the vermillion zone of the lip contains the same types of ceramides, cholesterol, and fatty acids found in other regions of epidermis, but the barrier function is weak, permitting a relatively high TEWL. There are sebaceous follicles in the connective tissue that supply sebaceous lipids to the lip surface. The morphology of the lips changes abruptly with increasing age.

TABLE OF CONTENTS

3.7.1 Vermilion zone/vermilion border

3.7.1 VERMILION ZONE/VERMILION BORDER

The lips represent a specialized transitional region in going from the skin to the oral mucosa. The line where the facial skin meets the surrounding the red external lip is known as the vermilion border of the lip. This term has frequently been misused to refer to the entire external red portion of the lip. The entire external red portion of the lip is referred to as the vermilion or vermilion zone. This vermillion zone has an underlying connective tissue that is more flexible than the connective tissue of most regions of the skin and is covered by a thin

orthokeratinized epithelium [1]. The underlying connective tissue has a rich blood supply, which contributes to the red coloration [2].

3.7.2 TEWL/HYDRATION

The projected area of the corneocytes on the vermillion zone of the lip is slightly larger than that of corneocytes from the cheek, and the TEWL through the lip is greater than TEWL through the cheek [3]. The transition from the exterior keratinized epithelium of the vermillion zone and the internal nonkeratinized epithelium is abrupt; however, the portion of the vermilion zone closest to the oral mucosa is sometimes referred to as the submucosa. Surprisingly, the hydration of the submucosa is less than the rest of the external vermillion zone [4]. Hydration of the upper lip is significantly greater than hydration of the lower lip.

3.7.3 SEBACEOUS FOLLICLES

Within the connective tissue along the vermillion border of the lip are sebaceous follicles, which are sebaceous glands without associated terminal hairs. The composition of the lipid mixture produced by these sebaceous follicles is the same as that produced by the major sebaceous glands of the skin [5]. The composition of sebum in the lumen of the gland is 57% triglycerides, 25% wax monoesters, 15% squalene, 2% cholesterol esters, and 1% cholesterol [6]. As sebum flows to and over the skin surface, the triglycerides undergo partial hydrolysis to release fatty acids, some of which are antimicrobial [7]. The most notable antimicrobial fatty acids are lauric acid (C12:0) and sapienic acid (C16:1Δ6). Sebaceous follicles are not only found in the vermillion border of the lip and in the oral mucosa, they encircle every orifice of the human body [7]. This distribution strongly suggests a protective function. In general, sebum secretion rates in adults decreases with increasing age. TEWL through the vermilion zone also decreases with age, but hydration appears to be independent of age [8].

3.7.4 STRATUM CORNEUM LIPIDS

As with other regions of the skin, the major lipids found in the *stratum corneum* of the vermilion zone are ceramides, cholesterol, and fatty acids. These lipids are

important in that they determine the permeability barrier function of the lips. The ceramides found here, as in other regions, are a complex mixture of structural types. Ceramides consist of a fatty acid amide linked to a long-chain base. The amide-linked fatty acids can be normal fatty acids, α-hydroxyacids, or ω-hydroxyacids, and the long-chain bases can be sphingosine/dihydrosphingosine, phytosphingosine, or 6-hydroxysphingosine. When the amide-linked fatty acid is an ω-hydroxyacid, a normal fatty acid is ester-linked to the ω-hydroxyl group.

A ceramide nomenclature system has been proposed in which the amide-linked fatty acid and long-chain base are each indicated by a single letter (normal fatty acid, N; α-hydroxyacid, A; ω-hydroxyacid, O; sphingosine/dihydrosphingosine, S; phytosphingosine, P; 6-hydroxysphingosine, H) [9]. The presence of an ester-linked fatty acid is indicated by a prefix E. In this system, a ceramide containing an α-hydroxyacid amide-linked to phytosphingosine would be ceramide AP. All nine possible structural types of ceramides have been detected in *stratum corneum* from the vermilion zone, and their relative proportions are similar to those found in other regions of skin. Weight percents of the ceramides from the *stratum corneum* of the vermilion zone are: EOS, 4.4; NS, 10.5; EOP, 0.7; NP, 23.3; EOH, 2.6; AS, 11.3; NH, 20.9; AP, 8.8; AH, 17.4.

3.7.5 CHANGE WITH AGE

A series of studies have demonstrated that the upper lip measured from the bottom of the nose lengthens with increasing age, while the vermilion zone becomes narrower [10–12].

We note that the literature has been comprehensively reviewed in this brief chapter and that not much work has been done in this area. This is will be of special interest to cosmetic and personal care scientists and formulators since products for lip care vary widely from moisturizers to lipstick. As such, we believe that lip care and beauty can be advanced considerably by providing a deeper understanding of the differentiation between “normal” skin and that of lip skin.

ABSTRACT

In this chapter we address head-on this rarely discussed substrate, in the best *Harry's Cosmeticology* tradition.

As we have seen in many other chapters in this book, the perception of beauty and its relationship to well-being and skin health are intimately connected. Recent work in the cosmetic and personal care field has now extended beyond mere ingredients and formulations to other factors that provide an impact on beauty in the wider sense.

With the growing advent of dermatologists, OB-Gyn professionals, and other medical researchers formulating their own product lines, we deem it appropriate and timely for a detailed discussion of the anatomy, function, dysfunction, and approaches to improve the perception and well-being of individuals who want to feel and project beauty in their world.

While many may begin with the thought that this body substrate is more intended for medical/drug intervention, the reader will see there is much opportunity for the development of cosmetic-based over-the-counter, natural approaches that offer enhancement of this category and are both needed and wanted by the world's female population.

3.8.5 A New Frontier
References

3.8.1 THE ANATOMY

Vulva includes female genital regions that are externally visible in the perineal

region composed of mons veneris, labia majora, labia minora, and clitoris.

- **Mons veneris,** overlying the symphysis pubis, is the fatty prominence covered by curly hair.
- **Labia majora** are composed of two longitudinal folds of skin extending in elliptical fashion to enclose the vulvar cleft. Contain abundance of adipose tissue, sebaceous glands, and sweat glands. Embryologically analogous to penile shaft of male genitalia and the skin covered by hair on their upper outer surfaces.
- **Labia minora** are thin, firm, pigmented, redundant folds of skin, which split anteriorly to enclose the clitoris and meet posteriorly by the vestibules. Skin of labia minora does not contain hair follicles and is poor in sweat glands but rich in sebaceous glands.
- **Clitoris** is a small cylindrical erectile organ at lower border of symphysis. It is made up of two crura, body and glans. Crura lie deeply, in close apposition to peri-osteum of ischiopubic rami. They join to form the body of the clitoris, which extends downward beneath a loose prepuce to be capped by the acorn-shaped glans. Only the glans of the clitoris is visible externally between the two folds formed by bifurcation of labia minora. The visible clitoris is one to two inches in length. It is attached to the pubic bone and separates into two crura that are each about two to four inches in length. Clitoral hood acts as a shield for the clitoral glans. The role of the clitoral hood is to provide protection from too much stimulation.

3.8.2 VULVAR INNERVATIONS: PHYSIOLOGICAL AND ANALYTICAL

Vulva and perineum are innervated by femoral nerve posterior and lateral margins of vulva along leg crease. Genitofemoral and ilioinguinal nerve from L-1 and L-2 innervate the mons pubis upper labia majora to the level of urethra. Perineal branch of pudendal nerve (S-2–S-4) covers the lobes of labia majora. A rich plexus of over 8,000 nerve endings covers the dorsal aspect of the glans clitoris from the deeper pudendal nerve. The inferior cuneal nerve from S-1–S-3 also covers the vulva.

Assessing Sensory Perception on the Vulva and on Extragenital Sites

Sensory perception on the vulva as well as extragenital sites occurs by means

of detection of transient light touch by Meissner corpuscles and transient deeper pressure by Pacini corpuscles. Slowly adapting receptors, such as Merkel cells and Ruffini receptors, are responsible in responding to more sustained touch, such as sensing texture or shape.

While perception of burning or itching appears to be unaffected with aging, vulvar sensitivity to mechanical stimuli declines after menopause.

However, of the various demographics (age, gender, ethnicity) and anthropometric variables (height, weight, size of the body), *the most significant effect on sensory perception is advancing age*. This is also true for sensitivity to vibration, thermal threshold, and mechanical stimuli. Ethnic differences in sensory perception also have been reported. For example, Japanese subjects were more sensitive to touch and pain on the cheeks and palm of hands than Caucasians. However, Japanese subjects rated pain as less severe on a subjective scale than Caucasians—despite being more sensitive at perceiving it. Cultural stoicism may have contributed to higher tolerance to pain (1).

A Canadian study of 40 premenopausal women found that the labium minora and the mucosa of the vulvar vestibule were less sensitive than the forearm to filament touch and pressure. Although the labium minora was more sensitive to pain than forearm (2), similarly, a study of 13 premenopausal women found vulvar vestibule to be less sensitive to filament touch and pressure than deltoid muscle, forearm, or thigh (3).

A Swedish study found the clitoris to be less sensitive to perception of vibration than dorsum of hand but more sensitive than dorsum of the feet (4).

A Turkish study on vibratory threshold found vulvar sites (labia majora and minora, clitoris and vaginal introitus) were comparable in sensitivity to the first and second fingers and to the nipples. In this study, lips and ears were the least sensitive to vibratory stimuli (5).

A study conducted in the USA of both healthy and neurologically impaired women (6) noted significant loss of sensitivity to pressure/touch in postmenopausal women, hypoestrogenic women, women with vulvar atrophy, neurologically impaired women, and women with impaired sexual function, all of whom showed clear effect of estrogen on vulvar sensitivity. Although vulva has lower density of estrogen receptors than vagina, the effect of estrogen on touch sensitivity appears profound (7). Estradiol treatment significantly increased sensitivity of vestibule to pressure/touch relative to placebo at four to

six weeks. Although the mechanism of action is not known at this time, the potential sensor neural targets may be C fibers of Merkel cells (8).

In a Canadian study of premenopausal women aged 18–45, it was found that sexual arousal had no effect on extragenital sensations, suggesting dyspareunia is not due to lack of arousal (9).

Thresholds to touch averaged over all vulvar sites (clitoris, labium minus, perineum, and anal verge) were noted to be 4.6-fold lower in normoestrogenic compared to hypoestrogenic women (10).

Because of the importance of sensation to female sexual well-being and the perception and projection of beauty, in its broadest sense, an objective of an appropriate vulvar skin regimen should include the maintenance of vulvar sensorium by preserving nerve sensitivity functions.

3.8.3 VULVAR ATROPHY: CAUSES AND PHYSIOLOGY

In the U.S., half of the population is expected to be over the age of 50 in the next 20 years. There is a misconception that skin disorder is only cosmetic. *Because physiological changes occur with skin, if the causes are left untreated, such disorders can lead to a vicious cycle of chronic irritation and pruritis. These changes affect sexual function, comfort, and self-esteem.*

Common physiological changes with age include:

lower elasticity and diminished tensile strength,
reduceda dermal thickness,
reduced vascularity and cellularity of dermis,
decreased sensory perception,
reduced hydration,
flattening of the dermal-epidermal junction,
reduced epidermal thickness,
increased permeability, and
slower wound healing.

An awareness of these facts will bring a new pathway to individuals and companies looking for new products, new categories, and a common wish to enhance all aspects of individual beauty. The intention here is to expedite work

in this area beyond the medical/drug approaches already in existence and to include the development, use, and application of cosmeceuticals, natural products, *etc.* that are having a positive impact on beauty enhancement.

Skin changes can be slow and progressive with loss of subcutaneous fat beneath mons veneris and labia majora. Skin becomes pale, dry, and frail with tissue of low elasticity and pliability. Minimal lubrication results, due to decreased blood flow. Vulva becomes increasingly shrunken in appearance while pubic hair becomes thin, sparse, and brittle. There is reduction in size of labia minora, clitoris, and prepuce. Vulvar tissue can be diminished, obliterated, or even fused, with irritation and erythema evident. Skin becomes thin, shiny, and inelastic. Microscopically there are decreases in epithelial thickness and vascularity, and decreases in nerve endings but increases in dermal fibrosis.

An increase in permeability with thinning of the protective epithelium can predispose the vulva to chronic atrophic vulvitis with inflammation and abrasion/fissures from repeated irritation. If uncorrected, this process can lead to progressive sclerosing atrophy with stenosis of the vaginal orifice and effacement of the labia minora and clitoris (Kraurosis vulvae).

Causes of Vulvar Atrophy:

By 2010, over 64 million women in the U.S. were over the age of 45. It is estimated that vulvar atrophy is a silent epidemic affecting up to 50% of postmenopausal women. Women suffer in silence with this chronic and progressive medical condition and its impact on quality of life, sexual function, and urogynecologic health. Left untreated, vulvar atrophy can cause personal and marital distress and contribute to female sexual dysfunction (11). Many are reluctant to discuss their concern due to embarrassment, cultural taboo, and uncertainty about treatment options. In our opinion, women’s quest for personal beauty goes far beyond how their face looks, what color and shape their hair is, and the degree of wrinkling they have.

Vulvar Changes:

These changes are the result of a loss of tissue elasticity and thinning as well as decreased vascularity and subdermal inflammation. After childbirth, darker pigmentation changes of vulvar region are also noted. Vulvar skin retracted with tissue demarcation between labia majora and minor becomes blunted. Fragile tissue becomes prone to cracking and splitting. Thinned vulvar skin loses much of its natural surface defense mechanism and is more likely to become and remain inflamed.

With chronic inflammation of the skin in this area, lichen sclerosis develops, involving skin and mucous membrane of vulvar and rectal area. With higher pro-inflammatory cytokines—interleukin-1, interleukin-6, and TNF alpha in older skin—inflammatory response is likely. The body responds to new inflammation with repair accompanied by vulvar and perineal itching, thereby causing a vicious cycle. *Further thinning of keratin layer of labia majora and minora decreases protection against bacteria and fungus, leading to chronic infection.*

Common causes of hypoestrogenic atrophy are natural menopause and surgical/chemo-or radiation-induced ovarian failure. Usage of maintenance endocrine therapies can also cause ovarian dysfunction and vulvar atrophy. One common example is aromatase inhibitor used by breast cancer patients.

Other causes of such atrophy include young women undergoing a gonadotropin-releasing hormone agonist or antagonist, which has induced a hypoestrogenic state. Breastfeeding women have diminished estradio level, causing atrophy and decreased libido. Furthermore, allergy sufferers with chronic antihistamine use and ones on parasympathomimetic or tricyclic antidepressant medications (12) will have similar symptoms. Still other causes include use of birth control pills, Sjorgen's syndrome, anorexia nervosa, bulimia, or infertility treatments.

3.8.4 TREATMENTS

American television is full of drugs designed to correct male erectile dysfunction. For women of such partners, there can be a significant downside if they suffer from vulvar atrophy. Coitus with vulvar atrophy can cause lower genital tract skin and mucous membrane laceration due to dryness and decreased elasticity. Pain will cause pelvic floor muscle contraction and reduced vaginal secretion. *Over-the-counter lubricants with propylene glycol and chemical preservatives can cause sensitivity to women with an inflamed mucous membrane, leading to more local inflammation and pain.* Other products can dry out over time with firm residual kernels to become an added source of irritation.

If progressive tissue changes of thinning and inflammation occur, effects of estrogen are less dramatic. Estrogen will accelerate healing and decrease inflammation but will not return the tissue to a premenopausal state. It is not a

fountain of youth but will halt further degeneration.

As developers of new cosmetic and personal care ingredients, formulations, and products, our goal is to alleviate symptoms/discomfort and improve the quality of life by minimizing or reversing physiological changes.

a. Over-the-Counter Treatments

A number of OTCs can be used by women with minimal symptoms who are concerned about hormone use or are not candidates for hormonal treatment. Definitive efficacy data are lacking for almost all of the OTCs. These products are vaginal moisturizers and lubricants, but none are designed for the vulva.

Some OTCs may contain irritating ingredients such as warming additives, dyes, perfumes, bactericides, spermicides, benzocaine, chlorhexidine, and preservatives (parabens and propylene glycol). Because petroleum-based products such as mineral oil and petroleum jelly can interfere with condom use, they are best avoided.

b. Pharmacologic Treatment:

Estrogen

Topical low-dose estrogen is considered first-line pharmacologic treatment. Progesterone is not indicated with low-dose topical estrogen. Although limited in data in randomized, controlled clinical trials, estrogen is noted to be effective. A position statement from North American Menopause Society (NAMS) provides an evidence-based conclusion and recommendation for local estrogen treatment. Furthermore, NAMS concludes that there are inadequate data to support annual endometrial sampling or transvaginal ultrasound in asymptomatic patients (13).

In a cohort study of 1500 previously treated patients with breast cancer, no statistically significant difference in disease-free interval between use and without usage of vaginal estrogen was noted (14).

Usage of vaginal ring and vaginal tablet estrogen showed no significant changes in endometrium (15). Similar results were confirmed by endometrial biopsy (16). Due to lack of long-term safety data, one needs to have well-documented informed consent to risk and benefits prior to prescribing local estrogen to a patient with a history of hormone-sensitive malignancy.

After publicity surrounding Women's Health Initiative Studies, there is less frequent use of Hormone Replacement Therapy (HRT) in the U.S. This NIH (National Institute of Health) sponsored study highlighted the potential danger of taking systemic HRT, with small increased risk of developing breast cancer in women taking HRT for five years or more. Greater chance of heart attack and stroke were also noted. This finding led to a precipitous drop in numbers American women using HRT. *Unfortunately, benefits were downplayed and risks were emphasized.*

NAMS recommendations for patients without hormonally sensitive tumors is that they should not be treated differently than routinely managed postmenopausal patients. To date, the FDA has not yet approved estrogen-based products for use in patients with hormonally sensitive malignancy.

c. Novel stem-cell-derived peptides

SERM (Selective Estrogen Receptor Modulator) Ospemifene

Recently, the FDA approved a non-estrogen oral medication known as ospemifene. Ospemifene is a selective estrogen agonist and antagonist depending on tissue type. It has been approved for dyspareunia. Common side effects reported include: hot flashes, muscle spasms, increased sweating, and increased vaginal discharge.

Compared with placebo in clinical trial, daily usage of ospemifene decreased incidence of dyspareunia by –1.55 from baseline standard deviation of 2.7 compared with decrease of –1.29 from baseline by placebo.

Because ospemifene can act as an estrogen in other organs, it carries a risk of endometrial cancer, stroke, and blood clots. It should not be used in breastfeeding or pregnancy or used together with coumadin, rifampin, ketokonazole, omeprazole, rifampin, or buproprion.

At higher dosages, ospemifene is associated with increase in thymoma, adrenal subcapsular cell adenoma, sex cord stromal tumors, granulose cell tumors, and luteoma tumors in animal studies.

Topical growth factors and peptides

As stated above, physiological changes occur with aging skin in this substrate as well. Issues we would like to address in formulating a cosmetic product include:

- Improved sensory perception
- Improved hydration

- Improved appearance in color and tone
- Improved elasticity and tone of skin
- Improved firmness and volume

Topical growth factors and peptides have played a role in reversing the aging process described above, although the main use of growth factors is in wound healing (56, 57). Kinetin was first isolated from Herring sperm DNA in 1955, with natural antioxidant properties.

Stem Cells: The New Frontier

In a manner similar to that described for Topical Growth Factors and Peptides, Adult Stem Cell Derived Cells have exerted in vivo *and* in vitro *effects that address the issues mentioned above.*

Stem cells are a population of immature tissue precursor cells capable of self-renewal and provision of multi-lineage differentiable cells for tissues. Adult stem cells have fewer issues compared with embryonic stem cells, such as difficulties in control of differentiation and issues relating to ethics. Stem cells provide a building-block function by moving to the injured area and differentiating into neighboring cells, and by replacing damaged cells. By secreting diverse growth factors, they activate the neighboring cells to exhibit diverse pharmacologic action (paracrine effect). Human subcutaneous adipose tissue is a promising source of adult stem cells that secrete various cytokines and growth factors. These in turn control and manage the damaged neighboring cells (18, 19). The figures below demonstrate these results, which include an increase in collagen and anti-wrinkle effects.

Anti-wrinkle effect:

Stem cells were injected subcutaneously into a UVB irradiation-induced -wrinkle. Reverse replica demonstrates wrinkle-diminishing effects.

a. control, b. 1 × 103, c. 1 × 104, d. 1 × 105 cells (23)

Figure 1 Stem Cells

Figure 2 Collagen-stained blue, demonstrating increase in collagen content with adult-derived stem cell. A: control, B: 1 × 10 3, C: 1 × 10 4, D: 1 × 10 5 (23).

Figure 3 Histopathology of pig skin 14 days after injection of ADSC (1×10 6. A denotes control; B represents treatment arm. Western blot noted 40× increase in collagen expression (22).

Stem cells are limited because collection is required and only autologous transplantation is possible. Injection is mandatory, with short life span out of body and a long time to manufacture. Adult-Derived Stem Cell secreted factors have advantages over ADSC in that ADSC can be difficult to handle, transport, and commercialize, and they have a short shelf life. There is also the threat of passing on viruses, diseases from other animal-source nutrients to cultured stem cells in the laboratory, uncontrolled growth, and misdirected growth, especially of embryonic cells.

Recently, novel processing has enabled mass production of quality-controlled peptides from adult stem cell growth mediums. Protein extracts from conditioned media are available with following key ingredients in sufficient concentration for efficacy:

TGF beta 1 (transforming growth factor)
PDGF (platelet-derived growth factor)
KGF (keratinocyte growth factor)
Basic FGF (fibroblast growth factor)
HGF (hepatocyte growth factor)
VEGF (vascular endothelial growth factor)
SOD (superoxide dismutase)

Figure 4

TABLE 1. Concentration of Cytokines and Extracellular Matrix Proteins	
Proteins	*Concentration*
PDGF	44.41 ± 2.56 pg/mL
bFGF	131.35 ± 30.31 pg/mL
KGF	86.28 ± 20.33 pg/mL
TGF-β1	103.33 ± 1.70 pg/mL
HGF	670.94 ± 86.92 pg/mL
VEGF	809.53 ± 95.98 pg/mL
Type I collagen	921.47 ± 49.65 ng/mL
Fibronectin	1466.48 ± 460.21ng/mL

Table 1, Reference (23)

These cytokines are needed in maintaining components of the dermis, promoting wound healing, stimulating collagen synthesis/secretion, regulating cell growth and division, promoting epithelial cell growth, promoting the formation of new blood vessels, stimulating and forming of new blood vessels, and providing protection of skin from oxidative damages.

In a clinical study using Adult Derived Stem Cell Protein Extract (AAPE; Proteomics Inc., Seoul, Korea) applied topically 12 times at two-week intervals for wrinkle indications, 47% of subjects showed good to excellent improvement, with 63% judged to have very good to excellent improvement. Cytokines were

injected intradermal into skin to evaluate efficacy in subsequent studies and exhibited confirmed efficacy.

One such peptide has been approved by U.S. CTFA as of September 2006 (Cosmetic Toiletry and Fragrance Association/ Personal Care Products Council) with the INCI name of Human Adipocyte Conditioned Media Extract (21343). Readers interested in learning more about peptides can consult another chapter on this subject in this text. Results for ADSC-derived factors are promising and might have potential in skin regeneration because can they can be manufactured in large scale with long-term stability while relatively devoid of safety issues (20, 21).

3.8.5 A NEW FRONTIER:

Adipose-derived stem cells and their secretory factors are a promising therapy for skin aging as reported in *Dermatologic Surgery* (Oct. 2008). Such products have been used on the face with good results in the author's clinical practice. Based on extrapolations from patients' subjective reports, and observation from past gynecological experience that the vulvar skin's rapid healing is due to a rich vascular supply similar to the face, formulations specifically designed for the vulvar region have been prepared containing such stem cells. *Initial results have shown a promising, positive, subjective response in restoration of sensitivity and skin quality. As such, these results represent a new frontier and direction for product developers interested in addressing the issues discussed in this chapter.*

Topical usage of adult stem cell secreted factor for wrinkle reduction. Daily application photos were taken four weeks apart. See Figures 5.

Figure 5 Topical usage of adult stem cell results

Figure 6 Improved firmness in periocular skin four weeks after injection of adult stem cell derived factor.

Figure 7 Improved firmness and color via injected adult stem cell derived factor four weeks after treatment.

About the Editor-in-Chief

Meyer R. Rosen

CChem, CPC, CChE, CFEI, DABFE, DABFET, FAIC

Meyer R. Rosen is President of Interactive Consulting, Inc. (www.chemicalconsult.com). He is a Thought-Leader and expert in the field of Technical Marketing and multi-industry Technology Transfer Applications including, but not limited to: cosmetics and personal care, applied rheology, applied surface and interfacial chemistry, polymers, organosilicones, professional editing and custom preparation of Mind-Maps® for the organization and presentation of complex information.

Mr. Rosen is a Chartered Chemist and Fellow of the Royal Society of Chemistry (London); a Fellow of the American Institute of Chemists and both a Nationally Certified Professional Chemist and Certified Professional Chemical Engineer. He is a member of the U.S. Society of Cosmetic Chemists (SCC) & the American Institute of Chemical Engineers. Meyer serves as an Advisor for David Smith, Executive Director of the SCC Advisory Committee. He is also Editor for U.S. & Canada and Editor-in-Chief for North and Latin America for Euro Cosmetics Magazine in Germany. Mr. Rosen is Editor of the Delivery System Handbook for Personal Care and Cosmetic Products and Editor-in-Chief of Harry's Cosmeticology,9 th Ed.

Meyer served for six years as the Chief Scientific Advisor and Director of Technical Programming for United Business Media's (UBM) HBA Technical Conferences. He was a former Director of the American Institute of Chemists, past Vice President of the Association of Consulting Chemists and has served on the Scientific Advisory Board of Supply Side West/East: Virgo Publications. Mr. Rosen is also the Founder, Organizer and co-moderator for HBA's Annual Interna-tional Safety, Regulatory and Certification Symposia.

Acknowledgements

I acknowledge the ongoing sense of calm thoughtfulness of Ben Carr, my wonderful publisher and his confidence and trust in my judgment while providing the special support that has meant so much to me, over the almost three years it has taken to produce the book you are reading today.

I also acknowledge and thank the many authors of this book for their commitment to making this the best Harry's ever written. They have taught me many things by their writings and provided superb networking contacts to people who had the background to write about the areas I saw as needing to be in the book. I am grateful for their growing friendship and relationship and providing me the opportunity to interact with many of the finest minds/people; and their thinking, as well as following my guidelines to achieve our goals.

I am also grateful for the many kind words from my authors and editors who liked my professional editing skills and sharpening them as I went along. Their patience in explaining- in writing- the answers to all of my seemingly endless questions contributed much to my understanding our industry in a way that was far more in depth than I brought to beginning this book. As I said to them, "If you can't explain it to me so I really understand it; then how will our readers understand what you are saying?

I give special thanks to my Editors who took my thoughts and ideas and worked with me to find authors who knew their subjects and could organize and combine the thinking of- the- many to produce a unified- whole. Special thanks also to Navin Geria, Howard Epstein, Chia Chen, Bruce Victor, Bozena Michniak-Kohn, Ruud Overbeek, Manuel Gamez-Garcia, Michael Prencipe, Chuck Warren, Lee Stapleton, Adam Friedman, M.D., Ray Rigoletto, Roger McMullen, Randy Wickett, Martha Tate and so many others who have contributed to this book.

Finally, I wish to thank my friend and colleague, Professor Doctor Johann Wiechers, former President of the IFSCC (International Federation of the Society of Cosmetic Chemists) who unfortunately, unexpectedly and oh-so-quickly passed from this life while on one of his numerous visits to countries around the world. Johann travelled to more countries than I can name, to encourage and support the IFSCC in its mission to bring beauty and health to the many through his clear

thinking, close, objective, ever-questioning and challenging examination of the "science" associated with cosmetics and personal care. Once upon a time, he told me that while travelling the world, he always stayed in the same type of room of his favorite hotel chain because "it always made him feel like he was at home."

A manager I once had told me that if "I had lemons, I should make lemonade". And so it was with Johann, who turned the enormous amount of time he spent in travelling to producing an incredible volume of questioning, challenging and probing scientific papers for us to read and think about for years to come.

Wherever you are, Johann, I want you to know that your work and critical thinking approach to cosmetic science has impacted us all- and we miss you greatly.

Dedication

This book is dedicated to my wife Selma, my Soulmate, Committed Listener and Partner in the Journey-of-Life.

She who knows, and reminds me, to put the past in the past in order to open the doorway to the creation of new possibilities and generate new directions for growth in areas we do not know that we do not know.

How remarkable it is
When mere words on paper
Grow together
Beyond themselves.

Such words as these
Are tracks in time.

Memories of a mind
Focused
A heart and soul
Ensconced.

—Meyer R. Rosen
July 4, 2014

Preface

Dear Reader:

This book is filled with highly technical and not-so-technical, but critical, information on the current state of the art in the cosmetic and personal care industry.

Before you jump into it, as I hope you will, for years to come, I take the liberty and license of providing some personal thoughts to let you know what motivated me in taking on this project, which has now been about two and a half years in the making.

If you had asked me if there ever would come a time that I would take on another major book project as large as the one I did about ten years ago (*Delivery System Handbook for Personal Care and Cosmetic Products: Technology, Applications, and Formulations*) . . . well, I would have gracefully declined.

However, as with many things in life, "everything has a season"—and there came a day that a soft-spoken, supportive man by the name of Ben Carr, Publisher of Chemical Publishing Company, offered me the opportunity to_be Editor-in-Chief of the widest-selling book in the cosmetic industry over the past sixty years! It was time to say yes, for in my heart, and for over thirty years, I had wanted to deepen my understanding, learn from, and then teach many of the brightest minds in the world about this intriguing area called Cosmetics. The reason it intrigued me is that the concept of creating beauty provides joy for us all in looking good and feeling good as a result.

Ralph Gordon Harry, FRIC, created the first edition of what later became *Harry's Cosmeticology*. At the time (1954) it was called *Cosmetics: Their Principles and Practices*. We believe he also authored the 2nd through the 6th editions as well. The 7th edition was published in 1982 and co-edited by J.B. Wilkinson, MA, BSc, CChem, FRSC, and R.J. Moore, BSc, CChem, MRSC, MIInfSc; followed by the 8th edition in 2000 by Martin M. Rieger, PhD, and now, the 9th edition by myself, Meyer R. Rosen.

The Preface of the first edition describes the evolution of the modern cosmetics industry, which was grounded in the needs of the military in World War II. Some of the areas Harry mentions as stimulants for cosmetic scientific and technological creativity included, but were not limited to, development of safe and efficacious

sun-screening agents for men marooned on liferafts or in the desert who might be subjected to very severe solar exposure without shelter; flashburn creams designed to protect exposed skin surfaces against burns ("commando makeup"); and anti-sunburn lipsticks. Soaps, shaving creams, toothpastes, and fragrances were also developed for the military.

On the home front, special toilet soaps and barrier creams were developed to reduce dermatitis and, at the same time, the value of cosmetics as a morale builder became recognized when it was claimed that they served to combat fatigue and that a dressing room in a factory might improve efficiency by as much as 10 to 15%. All these developments necessarily had repercussions in the cosmetic field and resulted in the synthesis and development of other cosmetic ingredients such as insect repellants, emulsifiers, detergents, antioxidants, preservatives, and more.

As we move forward sixty years to today's cosmetic needs and wants, there have, of course, been major shifts in what sources the development of cosmetics and personal care products. *It is this enormous shift that has motivated me to take on the job of Editor-in-Chief of the 9th edition of* Harry's Cosmeticology.

As I see things, the population of our world has increased dramatically—as has the breadth of its ethnic interchange. This trend is escalating exponentially. It now has spread from a women-only context to men as well. With it, the age of the population is increasing, benefited by the wonders of modern medicine, enormous breakthroughs in understanding the genetic code, and the beginnings of applying that understanding to further improving the health, well-being, and appearance of the old (at any age) yearning to be young(er). In fact, underneath this yearning, I assert, is the wish to live longer and perhaps, unspoken, to live forever.

I don't know if this will be possible someday, but I do know the yearning is there—recall, for example, the age-old search for the Fountain of Youth. What intrigues me is that nowadays, all the research on the skin to make it look younger is merely the surface of a deeper search to make our bodies younger inside as well as out.

If we put aside the regulations that separate cosmetics from drugs; if we put aside the ever-changing regulatory barriers that differ from one geographical area to another, we come, in my opinion, to the heart of the matter.

Whatever you want to call it, be it cosmetics, drugs, the search for medical breakthroughs etc., it is all the same need being expressed. We all want to reverse the "inevitable" impact of gravity and time on ourselves and our loved ones. My intention in becoming Editor-in-Chief of the current 9th edition of *Harry's* is to support that yearning in the best way I know how.

I believe we are at a tipping point in fulfilling this eternal search for youth. With the breakthroughs in understanding genetics, epigenetics, and biochemistry—as well as the enormous growing consumer pull, the need to develop approaches that really fulfill the longing to be young again is the opportunity of our lifetimes.

It is my pleasure to give you, in the best tradition of sixty years of *Harry's Cosmeticology*, the knowledge described and documented in this book. I give it to you for your study and to mentor future generations of beauty/youth-seekers in moving towards this goal.

Meyer R. Rosen

PART 1 IN THE BEGINNING

PART 1.1

MARKETING CONCEPTS TO EMPOWER TECHNICAL PEOPLE

Darrin C. Duber-Smith, MS,
MBA Senior Lecturer Metropolitan State University Denver

TABLE OF CONTENTS

1.1.1	The Magic and Mythology of Marketing	3
1.1.2	The Marketing Concept	4
1.1.3	Assessing the Marketing Environment	4
1.1.4	The Four P's	6
1.1.5	Development, Prototypes, Testing, and Commercialization	8
1.1.6	The Truth About Innovation	9
1.1.7	The Missing Links	11

PART 1.2

CREATING THE RIGHT FRAGRANCE FOR YOUR PERSONAL CARE PRODUCT

Jill B. Costa, Ph.D.
Bell Flavors and Fragrances
500 Academy Drive
Northbrook, IL 60062

TABLE OF CONTENTS

1.2.1 The Fragrance House 15
1.2.2 Fragrance Materials 19
1.2.3 What is a Fragrance Composition? 21
1.2.4 Creation / Construction of Fragrances 22
a. Top, Middle, and Base Notes 22
b. Fragrance Characters 23
1.2.5 Interaction of Fragrance Materials with Product Bases 23
a. Volatility / Boiling Point 24
b. Hydrophobicity / Hydrophilicity (Octanol-Water Partition Coefficient, log K_{OW}) 24
c. Odor Detection Thresholds 26
1.2.6 Evaluation of Fragrances 30
a. Product-Use Cycle 30
b. Fragrance Complexity 32
1.2.7 Limitations of Fragrances 32
1.2.8 Cost Structure of Fragrances 32
a. Carriers 33
b. Concentration-Cost Considerations for Fragrances 33
1.2.9 Troubleshooting Fragrances 34
a. Color Changes 35
b. Physical Product Stability 35
c. Odor 35
1.2.10 Fragrance Types Defined 36

PART 2 REGULATORY

PART 2.1

REGULATORY REQUIREMENTS, INTELLECTUAL PROPERTY AND ACHIEVING GLOBAL MARKET SUCCESS FOR COSMETIC PRODUCTS 72

Co-Editors' Introduction
Ruud Overbeek and Meyer R. Rosen

PART 2.2

AN OVERVIEW OF THE CHANGING REGULATORY LANDSCAPE IN THE U.S AND THE E.U. AND HOW TO DEAL WITH THEM...

Dr. Matteo Zanotti Russo
University of Pisa
Angel Consulting SAS Milano

TABLE OF CONTENTS

2.2.1 The challenge of "changing standards" 78
2.2.2 Regulatory Requirements for Cosmetics in the United States 80
a. Introduction: roles and responsibilities 80
b. Rules and references 81
c. Definition of Cosmetic, field of application, drugs and cosmetics, cosmeceuticals 82
d. Classification of Cosmetic/Drug 82
e. How to manage Cosmetic/Drug 83
f. Cosmetics and Soaps 83
g. Labeling and package of cosmetics 84
h. Warnings 86
i. Missing INCI name; what to do 88
j. How to get the assignment of a new INCI name 88
2.2.3 Guide to Cosmetic Development and Safety Evaluations 88
a. Compliance of limited/regulated ingredients 88
b. Safety assessment of cosmetics according to FD&C Act 89
c. Regulated/limited substances 89
d. Prohibited ingredients and impurities according to the FDA 90
e. Color additives 91
f. Safety profile of substances: source of information 92
g. Safety profile of finished product 93
h. Microbiological requirement 94
i. Activity of manufacturers/importers/exporters 94
j. FDA plant inspection checklist 94
k. Activity of public health authorities: notification/permissions, audits 95
l. Future developments of U.S. legislation 95
2.2.4 Regulatory Requirements for Cosmetics in the European Union 95
a. Introduction, roles, and responsibilities 95

b. "Intercontinental" products 96
c. Classification of cosmetic/drug, borderline products 96
d. Roles and Responsibilities 97
e. Definition of "safety" 98
f. Labeling 98
g. Troubles on EU INCI names, and what before and after the "Glossary" 101
h. Guidelines on labeling 101
i. Manufacture of cosmetics for the European market 101
2.2.5 PIF and safety assessment of European cosmetics 103
a. Profile of the safety assessor 103
b. The structure of documents 104
c. Annex I: CPSR 104
d. Annexes that have to be considered: II to VI 106
2.2.6 Safety profile of substances: source of information 106
2.2.7 The safety assessment from raw material to finished product 108
a. Animal Testing 109
b. CMR 110
2.2.8 The Notification in the CPNP 110
2.2.9 Market Surveillance, activity of EU Authorities (Articles 22-23), RAPEX 111
a. Other laws that affect the EU 1223/2009: REACH (EU regulation on chemicals) 112
2.2.10 Practical features: how to move towards compliance with EU regulations 113
Conclusions 116
References 118

PART 2.3.1

ACHIEVING GLOBAL MARKET ACCESS - FOCUS ON RUSSIA

Ramzia Lefebvre
Technical Manager for Russia and Customs Union Certification
Intertek France
Government & Trade Services

TABLE OF CONTENTS

2.3.1.1 Introduction 121
2.3.1.2 What is the customs union and what is its aim? 122
2.3.1.3 What were the old requirements and procedures of product Conformity assessment and how have they progressed to date? 122
1. Prior to July 1, 2012 122
2. Since July 1, 2012 124
2.3.1.4 Overview of the new customs union technical regulation "about safety of perfumery and cosmetic products" 124
1. Definition of perfumes and cosmetics according to CU Technical Regulation 124
2. Conformity assessment documents 124
a. State registration 124
b. TR declaration of conformity to customs union 125
3. Requirements for perfumes and cosmetics 126
4. Labeling requirements 126
5. Mark of conformity 127
2.3.1.5 How different are the new rules from European requirements? 128
2.3.1.6 Do the new rules simplify access to the combined Russian and cu market? How do new rules affect exports of cosmetics to Russia? 130
2.3.1.7 Business climate in Russia and reforms—Russia joined WTO 131

THE HAIR 330

Editors Overview
Editor: Manuel Gamez-Garcia

Ashland Specialty Ingredients

PART 3.3.1

AN OVERVIEW OF THE PHYSICAL AND CHEMICAL PROPERTIES OF HAIR AND THEIR RELATION TO COSMETIC NEEDS, PERFORMANCE AND PROPERTIES

Manuel Gamez-Garcia
Ashland Specialty Ingredients

TABLE OF CONTENTS

3.3.1.1 Introduction 334
3.3.1.2 Chemical composition of hair 335
3.3.1.3 Main types of hair cells 336
3.3.1.4 Cortical cells and their role in hair properties 339
a. Cortical cell structure and composition 339
b. Viscoelasticity in hair and cortical cells 340
c. Shape-memory properties of hair 344
d. Viscoelasticity and the shape-memory properties of hair 345
e. Water and moisture absorption/desorption by hair and cortical cells 347
3.3.1.5 Different types of cortical cells and hair shape 349
3.3.1.6 Cuticle cells and their role in hair properties 350
a. Cuticle cell structure and composition 350
b. Viscoelasticity in hair and cuticle cells 354
c. Water and moisture absorption/desorption by cuticle cells 356
d. Optical properties of cuticle cells 358
e. The medulla cells 361
3.3.1.7 Melanin pigments in hair 362
3.3.1.8 Hair function 364
3.3.1.9 The follicle 364
a. Different zones in the follicle 365
b. Life cycle of the follicle 365

References 368

PART 3.3.2

AN OVERVIEW OF HAIR FOLLICLE ANATOMY AND BIOLOGY

Paul Mouser Ph.D.
Ashland, Inc., Ashland Specialty Ingredients, Bridgewater, NJ, United States

TABLE OF CONTENTS:

3.3.2.1 Hair Follicle Structure 377
3.3.2.2 Hair Follicle Cycling 380
3.3.2.3 Aging of the Hair Follicle 382
Conclusion 384

PART 3.3.4

MECHANISMS OF CHANGES IN HAIR SHAPE

Manuel Gamez-Garcia
Ashland Specialty Ingredients

TABLE OF CONTENTS:

3.3.4.1 Introduction 411
3.3.4.2 The shape memory properties of hair 412
a. Definition of shape memory materials 412
b. Hair is a biopolymer with shape memory properties. 414
c. Temporary shape memory in hair 415
d. The apparent permanent shape in hair 416
e. Permanent shape memory in hair 417
f. Changes to the permanent shape of hair 420
g. Shape reversion 420
3.3.4.3 Changes in hair shape by water-setting 421
a. The process 421
b. Physical processes taking place inside hair during water-setting 421
c. Temporary shapes induced by long-term deformations 423
d. Limitations of water-setting 424
3.3.4.4 Changes in hair shape by hot iron treatments 425
a. Introduction 425
b. The process 427
c. Mechanical action of the hot iron 428
3.3.4.5 Physical processes taking place inside hair during hot ironing 430
a. Water evaporation 430
b. Phase changes and transitions in hair 430
c. The mechanisms of water and hot iron setting are different. 431
d. Hot iron setting: partial denaturation of crystalline phase and vitrification of the amorphous phase 432
e. Heat transfer from hot iron to hair 436
f. Unwanted consequences of friction and rising hair

temperature above Tg 438
3.3.4.6 Hair shape changes induced by permanent waving solutions 440
a. The process 440
b. Physical and chemical processes taking place inside hair during permanent waving 441
3.3.4.7 Hair shape changes induced by alkaline relaxers 443
a. The process 443
b. Physical and chemical processes taking place inside hair during alkaline straightening 445
c. shapeless hair a new straight shape 449
3.3.4.8 Hair shape changes induced during grooming practices 452
a. Static vs. dynamic changes in hair shape 452
b. Friction vs. bending forces in dynamic changes in hair shape 452
3.3.4.9 Hair volume and changes in hair shape 454
a. Definition of volume 454
b. Main challenges in creating volume 455
c. Back-combing and "static fly away" 457
3.3.4.10 Frizz in hair and changes in shape 460
3.3.4.11 Body in hair and changes in hair shape 461
3.3.4.12 Hair shape changes induced by styling polymers 464
3.3.4.13 Role of styling polymers in changing hair shape 465
a. Temporary setting of hair with aerosols 466
b. Temporary setting of hair with gels and mousses 467
c. Mechanical properties of welding seams and spots 468
d. Effect of polymer glass transition temperature (Tg) on styling 469
e. Adhesive strength at the polymer/hair interface 471
References 473

PART 4.1.6

INGREDIENTS TO STRENGTHEN SKIN BARRIER INTEGRITY: FROM ALGAL PROTECTIVE EXOSKELETON TO A PROTECTIVE BARRIER FOR THE EPIDERMIS

Author:
Alexandra Jeanneau
Scientific communication officer, Alban Muller Group

TABLE OF CONTENTS

4.1.6.1 Skin barrier and epidermis organization overview 695
a. Epidermis cell structures for skin resistance and cohesion 696
b. Cell structures depending on calcium 697
c. Calcium's information-signaling properties 698
4.1.6.2 Solution for alterations in epidermis 699
a. Epidermis structures responsible for epidermis resistance 699
b. Improving calcium bioavailability 700
4.1.6.3 A natural ingredient to strengthen skin barrier integrity inspired by an alga's primitive strategy 702
a. A primitive strategy involving calcium 702

b. An ingredient with a unique mode of action **703**
c. Stimulation of calcium-depending cell structures **704**
1. Cytokeratin synthesis **704**
2. Desmosome formation **705**
d. Restoring intercellular communication, a key factor of the epidermis functioning **706**
e. Improving skin barrier integrity: a better protective shield against pollution **707**
Conclusion **708**
Glossary **709**

PART 4.2.3.2

SILICONE ELASTOMER APPLICATIONS

Author:
John Gormley
Director of Regulatory Affairs /QA
Grant Industries
103 Main Avenue
Elmwood Park, NJ 07407 USA

TABLE OF CONTENTS:

4.2.3.21 Silicone Elastomers for Improved Consumer Acceptance of a Product: Achieving the "WOW" effect 868
4.2.3.22 Cosmetic Attributes Texture and Oil Control (Mattifying) 870
4.2.3.23 Example Cosmetic Formulas with Silicone Elastomers 871
4.2.3.24 Summary 874
References 874

PART 4.2.4

SKIN WHITENER INGREDIENTS

Author:
Herve Offredo, MSc in Microbiology, MBA in Management and Finance
Senior Vice President Sales and Marketing
Barnet Products
140 Sylvan Avenue
Englewood Cliffs, 07632 NJ

TABLE OF CONTENTS:

4.2.4.1 Historic Evolution of Whitening Products in Japan 876
4.2.4.2 What Is a Whitening Quasi-Drug? 877
4.2.4.3 What Are the Quasi-Drug Additives? 883

a. In the melanocytes 884
b. In the keratinocyte 886
c. In the nervesa new approach to the reduction of dark spots 887
d. For the corneocytes 889
Conclusion 889
References 890

PART 4.2.5

MARINE INGREDIENTS FOR SKIN CARE: AN OCEAN OF RESOURCES

Author:
Herve Offredo
MSc in Microbiology, MBA in Management and Finance
Senior Vice President Sales and Marketing
Barnet Products
140 Sylvan Avenue
Englewood Cliffs, 07632 NJ

TABLE OF CONTENTS:

4.2.5.1 Marine resources 892
a. What is an alga? 892
b. Plants from the shore 894
c. Other resources from marine origins 895
4.2.5.2 Examples of the use of macroalgae in cosmetics 896
a. Moisturization 896
b. Slimming 897
c. Fountain of youth 898
d. Oligosaccharides 898
4.2.5.3 Examples of the use of microalgae in cosmetics 900
a. Exopolysaccharides 900
b. Photolyase 902
c. Thioreduxine/thioreduxine reductase 903
4.2.5.4 Examples of the use of coastal plants in cosmetics 905
a. Retinol-like 905
b. The discovery of AQP 8 905
Conclusion 906
References 906

PART 4.2.6

TOPICAL REDUCTION OF VISIBLE SKIN DETERIORATION DUE TO CELLULITE

Authors:
Peter T Pugliese, MD, 7139 Bernville Road, Bernville, PA 19506
Michael Q. Pugliese, LE, Circadia by Dr Pugliese 8371 Route 183
Bethel, PA 19507

TABLE OF CONTENTS:

4.2.6.1	**A Possible Etiology for Cellulite**	**909**
4.2.6.2	**The Menstrual Cycle**	**912**
4.2.6.3	**The Matrix Metalloproteinases**	**913**
4.2.6.4	**The Menstrual Cycle, MMPs, and Ovulation**	**913**
4.2.6.5	**The MMPs and the Menstrual Cycle**	**914**
4.2.6.6	**The key step relating menses to the genesis of cellulite**	**915**
4.2.6.7	**Topical Therapy for Reversing the Appearance of Cellulite**	**915**
	a. Chysinan aromatase inhibitor	**916**
	b. Chrysin	**916**
	c. DIM, or Diindolymethane	**917**
4.2.6.8	**Agents That Block MMPs**	**917**
4.2.6.9	**Mobilizing Adipose Tissue**	**917**
4.2.6.10	**Blocking Phosphodiesterase**	**918**
4.2.6.11	**Shuttling Fat into Mitochondria**	**918**
4.2.6.12	**Rebuilding Collagen**	**919**
4.2.6.13	**Collagen Stimulators**	**919**
4.2.6.14	**Clinical Studies**	**919**
Conclusion		**922**
References		**922**

PART 4.3.1

TOPICAL RETINOIDS

Author:
Aanand N. Geria, MD

TABLE OF CONTENTS:

4.3.1.1	**Introduction**	**926**
4.3.1.2	**Pharmacology**	**926**
4.3.1.3	**Indications**	**926**
	a. Acne	**926**
	b. Melasma and Post-Inflammatory Hyperpigmentation	**927**
	c. Photo-Aging	**927**
4.3.1.4	**Adverse Effects**	**927**
References		**928**

PART 4.3.2

PEPTIDES FOR ANTI-AGING SKIN CARE

Author:
Howard Epstein, Ph.D.
EMD Chemicals
One International Plaza, Philadelphia, PA 19113

TABLE OF CONTENTS:

4.3.2.1	**Peptides for Anti-Aging Skin Care**	**930**
4.3.2.2	**What is a peptide?**	**930**
4.3.2.3	**Skin Structure and Peptide Categories**	**931**
4.3.2.4	**Bioactive Peptides Marketed for Skin Care Products**	**934**
Conclusion		**937**
References		**937**

PART 4.3.3

MICRORNAS IN SKIN PHYSIOLOGY

Authors:
Jean-Marie Botto (Ph.D.), Valre Busuttil (Ph.D.), Florian Labarrade (M.Sc.), Catherine Serre (M.Sc.), Laurine Bergeron (M.Sc.), Christophe Capallere (M.Sc.), and Nouha Domloge (M.D.)
Ashland Specialties France, Global Skin Research Center, Upstream Research, Sophia-Antipolis, France.

TABLE OF CONTENTS:

4.3.3.1	RNA interference and microRNAs timeline of the discoveries	941
	a. Discovery of microRNAs	942
	b. The concept of RNA interference	943
4.3.3.2	MicroRNAs - nomenclature, structure, function, mechanism of action	944
4.3.3.3	MicroRNAs regulate various aspects of human physiology and epigenetics	946
4.3.3.4	MicroRNAs and skin physiology	947
	a. Introduction on skin	947
	b. MicroRNAs and cutaneous biology	948
	c. Epidermal renewal and skin barrier	949
	d. MiR-203 is a master regulator of epidermal differentiation	950
	e. P63, SOCS3, Zfp281, JUN, and ABL1 are the major mir-203 targets in the epidermis	950
	f. Other microRNAs important in epidermal renewal	951
	g. Skin pigmentation	952
	h. Dermal physiology	954
	i. MicroRNAs and the hypodermal adipocytes	955
	j. Hair follicle morphogenesis	957
4.3.3.5	Interest of microRNAs in the evaluation in vitro of anti-aging dermo-cosmetic ingredients	958
	a. Skin aging	958
	b. MicroRNAs and cellular senescence	958
	c. Tissue-engineering and microRNA studies	961
Conclusion		962
References		963
Glossary		973

PART 4.3.4

AMINO ACIDS

Author:
Bruce W. Gesslein
Technical Manager, Specialty and Personal Care
Ajinomoto North America, Inc.
400 Kelby St, Fort Lee NJ 07024 USA

TABLE OF CONTENTS:

4.3.4.1	**Overview of Amino Acids**	**977**
	a. Production	**977**
	b. Properties	**979**
4.3.4.2	**The Appearance of Aging of Skin and Hair**	**985**
	a. Skin	**986**
	b. Wrinkling	**988**
	c. Elasticity	**989**
	d. Clarity	**990**
	e. Hydration	**991**
	f. UV Damage	**995**
4.3.4.3	**Hair**	**995**
	a. Breakage	**995**
	b. Dullness	**998**
	c. Elasticity	**999**
	d. Roughness	**1000**
4.3.4.4	**Formulation for Skin Care**	**1003**
	a. Cleansers	**1003**
	b. Moisturizers	**1008**
	c. Serums	**1010**
4.3.4.5	**Hair Care**	**1011**
	a. Shampoos	**1011**
	b. Conditioners	**1013**
Conclusion		**1014**

PART 4.3.5

AHAS AND BEYOND: ANTI-AGING INGREDIENTS AND THEIR BENEFITS FOR ALL LAYERS OF THE SKIN

Editor:
Ronni L. Weinkauf, Ph.D.
VP, Applied Research Hair, Skin, and Makeup
L'Oreal USA
111 Terminal Ave
Clark, NJ

Contributing Authors:

Peter Konish
Director of Sensory and Formulation Development
NeoStrata Company, Inc
307 College Road East
Princeton, NJ 08540

Stacy S. Hawkins, Ph.D.
Global Clinical Leader
Unilever Research and Development
50 Commerce Drive, Trumbull, CT 06615

Uma Santhanam, Ph.D.
Senior Manager, Cell Biology and In Vitro Toxicology
Avon Products, Inc.
One Avon Place
Suffern, NY 10901

TABLE OF CONTENTS:

4.3.5.1 Introduction 1019
4.3.5.2 Alpha-Hydroxy Acids (AHAs) 1020
4.3.5.3 Quantitative Clinical Benefits of AHAs 1021
4.3.5.4 Cellular and Structural Changes Associated with AHAs 1027
4.3.5.5 Polyhydroxy Acids (PHAs) 1035
4.3.5.6 Bionic Acids (BAs) 1037
4.3.5.7 Formulation Strategies for Maximizing Hydroxy Acid Performance 1040
4.3.5.8 N-Acetylamino Sugars 1046
4.3.5.9 N-Acetylamino Acids 1052
Conclusion 1054
References 1055
Glossary 1062

PART 4.3.6

CYTOKINES, GROWTH FACTORS, AND STEM CELLS: NEWEST APPROACHES TO YOUNGER LOOKING SKIN

Authors:
Sarah A Malerich, BS, Lake Erie College of Osteopathic Medicine, 5000 Lakewood Ranch Blvd, Bradenton, Florida, 34211
Nils Krueger, PhD, and Neil S. Sadick, Sadick Dermatology Research Group, 911 Park Avenue, Suite 1A, New York, New York, 10075

TABLE OF CONTENTS:

4.3.6.1 Aging 1065
4.3.6.2 Growth Factors and Cytokines 1065
4.3.6.3 Stem Cells 1067
Conclusion 1069
References 1069

PART 4.3.7

ANTIOXIDANTS IN COSMETICS FOR ANTI-AGING

Author:
Ratan K. Chaudhuri
Sytheon Ltd.,
Boonton, New Jersey

TABLE OF CONTENTS:

4.3.7.1 Background 1073
4.3.7.2 Causes of UV-Induced Chemical and Biochemical Changes in Skin 1074
4.3.7.3 Antioxidants in the Defense System of the Skin 1077
4.3.7.4 Consequences of UV-Induced Chemical and Biochemical Changes in Skin 1078

4.3.7.5 Use of Conventional and Nonconventional Antioxidants for Skin Protection and Reversal of Signs of Aging 1080
a. Conventional Antioxidants 1080
b. Other Photoprotectants 1084
Conclusion 1087
References 1088

PART 5.0

FUNDAMENTALS OF SKIN ANTI-AGING OVERVIEW

Editor:
Navin M. Geria, Doctors Skin Prescription (DSP),
Senior Technical Advisor & Principal
DSP- Doctors Skin Prescription
34 Mountainview Road, Warren, NJ 07059

Howard Epstein Ph.D., EMD Chemicals, Philadelphia, PA

PART 5.1

THEORIES OF AGING SKIN ANTI-AGING: AT THE TIPPING POINT

Navin M. Geria, Doctors Skin Prescription (DSP),
Senior Technical Advisor & Principal
DSP- Doctors Skin Prescription
34 Mountainview Road, Warren, NJ 07059

TABLE OF CONTENTS:

5.1.1 Theories of Aging 1102
a. Wear and Tear Theory (Immunological Theory) 1102
b. The Neuro-Endocrine Theory 1103
c. The Genetic Control Theory 1103
d. The Free Radical Theory 1104

e. Mitochondrial Theory 1104
f. Waste Accumulation Theory 1105
g. Hayflick Limit Theory 1105
h. Death Hormone Theory 1105
i. Caloric Restriction Theory 1106
j. The Cross-Linking Theory 1107
k. The Telomerase Theory 1108
l. Glycation Theory 1108
m. Mutation Accumulation and DNA/RNA Damage 1109
n. Deficient Immune System/Autoimmune Theory 1109
o. Inflammation Theory 1109
Conclusions 1110
References 1111

PART 5.2

THE CELLULAR WATER PRINCIPLE

Author:
Howard Murad, MD
2121 Rosecrans Avenue, 5th Floor
El Segundo, CA 90245

TABLE OF CONTENTS:

Theories of Aging and Cellular Water 1114
5.2.1 What is aging, from a physiological perspective? 1114
5.2.2 Why do we age? 1116
5.2.3 Water loss and membrane hypothesis of aging 1116
5.2.4 The Science of Cellular Water 1117
Conclusion 1119
References 1121

PART 5.3

ANTI-SENESCENCE: ACHIEVING THE ANTI-AGING EFFECT BY MANAGING CELLULAR FUNCTIONS

Authors:
Shyam Gupta, Ph.D.
Bioderm Research
Linda Walker
CoValence, Inc.

TABLE OF CONTENTS:

5.3.1 Role of Cellular Senescence and Apoptosis in Skin Aging 1125
5.3.2 Role of Enzyme Dysfunction in Skin Aging 1126
a. Oxidative Stress and Free Radicals 1126
b. Peroxisomes 1127
c. Immunosenescence 1127
d. Advanced Glycation End Products (Ages) 1127
e. Proteasomes in Cellular Anti-Senescence 1128
f. Mitochondrial Free Radical Theory of Aging (Mfrta) 1132
5.3.3 Anhydrobiosis and Skin Aging 1133
5.3.4 Osmoprotection, Cellular Anti-Senescence, and Skin Anti-Aging 1134
a. Hyperosmarity, Inflammation, and Cellular Senescence 1135
b. Chemical Basis of Hyperosmarity 1136
5.3.5 New Peptide Derivatives for Anti-Senescence and Skin Anti-Aging 1139
a. Chemical Discovery 1139
b. Formulation Methodology 1141
5.3.6 Consumer Perception and Marketing of Enzyme Biology-Based Skin Care Products 1143
References 1143

PART 5.4

GLYCATION, PROTEASOME ACTIVATION, AND TELOMERE MAINTENANCE

Author:
Karl Lintner, PhD
President of Kal'idees S.A.S.

TABLE OF CONTENTS:

5.4.1 Glycation 1147
- **a. Measurement of AGEs 1149**
- **b. Prevention and/or Reversal of Glycation/Glycoxidation 1150**
- **c. In vitro data 1154**
- **d. Ex vivo data on explants 1154**
- **e. In vivo studies 1155**
- **f. Conclusion 1156**

5.4.2 The Proteasome 1156
- **a. Introduction 1156**
- **b. Cosmetic approach to proteasome activity 1157**
- **c. The study of the LC3-II protein 1159**
- **d. Caveat 1160**

5.4.3 Telomeres 1161
- **a. Introduction 1161**
- **b. Telomere length and aging 1162**
- **c. Senescence 1164**
- **d. Cosmetic ideas on telomere maintenance 1165**

Conclusion 1168
References 1168

PART 5.5

SIRTUINS AND SKIN

Authors:
Edward Pelle, Este Lauder Research Laboratories;
Melville, New York
Nadine Pernodet, Environmental Medicine,
New York University School of Medicine

TABLE OF CONTENTS

5.5.1	**Introduction to sirtuins**	**1178**
5.5.2	**Organelle-specific biochemistry of sirtuins**	**1180**
5.5.3	**Sirtuin response to environmental changes**	**1183**
5.5.4	**Application of sirtuins to anti-aging skin care**	**1185**
References		**1186**
Glossary		**1189**

PART 5.6

EPIGENETICS OF SKIN AGING

Author:

Rebecca James Gadberry
Senior Instructor & Program Coordinator,
Cosmetic Sciences, UCLA Extension
Consultant, Skin Care Strategy, Brand & Product Development

TABLE OF CONTENTS:

5.6.1	**The Human Genome Project Gives Birth To The Epigenetic Revolution**	**1192**
5.6.2	**Epigenetics Defined**	**1194**
5.6.3	**Two Primary Epigenetic Mechanisms**	**1195**
	1. DNA methylation	**1196**
	2. Chromatin remodeling and histone modification	**1200**
5.6.4	**Epigenetic Links To Aging**	**1202**
5.6.5	**Epigenetics And Aging Skin**	**1205**
5.6.6	**Epigenetics Mechanisms In DNA Damage and Repair**	**1210**
5.6.7	**Cosmetic Ingredients As Epigenetic Modifiers**	**1211**
5.6.8	**Nutriepigenetics: How Diet Alters the Epigenome**	**1213**
5.6.9	**Epigenetics: The Unifying Theory Of Aging?**	**1217**
5.6.10	**What the Future Holds**	**1218**
References		**1220**
Glossary		**1227**
List of Figures		**1239**

PART 5.7

CHRONOBIOLOGY OF THE SKIN SKIN CIRCADIAN RHYTHM AND CLOCK GENES: A NEW APPROACH TO SLOWING DOWN THE AGING PROCESS

Authors:

Nadine Pernodet, Ph.D. Vice President of Skin Biology Research
Edward Pelle, Ph.D. Director, Skin Biology Research
Este Lauder Research Laboratories
Melville, NY, US

TABLE OF CONTENTS:

5.7.1 Introduction to Circadian Rhythm and Clock Genes 1242
5.7.2 Desynchronization: Causes and Impact 1245
5.7.3 Skin Circadian Rhythm 1246
References 1250

PART 5.8

STRESS, SLEEP AND EPIGENETIC ORTHODONTICS: NEW DIRECTIONS FOR NON-SURGICAL SKIN ANTI-AGING

Author:

Dr. Barry Chase DDS

TABLE OF CONTENTS:

5.8.1 Sleep, Sleep Deprivation, Sleep Disorders, and Skin Aging 1257
a. Normal Sleep—Sleep Stages and Sleep Cycles: 1258
b. Sleep Latency 1258
c. Sleep Stage N1 1259

	d. Sleep Stage N2	1259
	e. Sleep Stage N3	1259
	f. Rapid Eye Movement (REM) Sleep	1260
	g. Sleep Disorders, Chronic Stress, and the Impact on Aging and Skin	1260
	h. The Pathophysiology of Stress the Hyper-Arousal of the Autonomic Nervous System	1260
	i. Sleep and Chronic Stress	1262
	j. Insomnia	1262
	k. Obstructive Sleep Apnea	1263
5.8.12	Sleep, Aging, and Aging Skin	1266
	a. Sleep Quality and Sleep Deprivation	1266
	b. Circadian Rhythm	1267
	c. Sleep, Human Growth Hormone: Aging and Skin	1268
	d. Chronic Stress and Sleep; Cortisol, Epinephrine, Aging, and Skin	1268
	e. Epinephrine and the Skin	1269
	f. Free Radicals, Sleep and Aging	1270
5.8.13	Therapy	1270
	a. Insomnia	1271
	b. Non-medical Cognitive Behavioral Therapy	1271
	c. Sleep Hygiene	1271
	d. Obstructive Sleep Apnea (OSA) and Aging	1273
	e. C-PAP Therapy	1273
	f. Oral Appliance Therapy (OAT)	1274
Conclusion		1274
Part 5.8.2	Epigenetic Orthodontics and Dento-Facial Orthopedics: Non-surgical Facial Esthetic Therapy	1275

ORAL CARE: FORMULATING PRODUCTS AND PRACTICES FOR HEALTH AND BEAUTY

Editor:
Caren M. Barnes
Professor Coordinator of Clinical Research
University of Nebraska Medical Center College of Dentistry

Contributors:
Chi Shing Wong
Member, Product Development Group
Colgate-Palmolive Global Toothbrush Division

James G Masters, Ph.D.
Director in the Research and Development Division
Colgate-Palmolive Company

Shira Pilch, Ph.D.
Associate Director: Research and Development Division
Colgate-Palmolive Company

Michael Prencipe, Ph.D.
Director in the Research and Development Division
Colgate-Palmolive Company

TABLE OF CONTENTS:

6.18 Introduction 1445
A. Important Issues in Oral Health 1445
B. Importance of Aesthetics in Dentistry 1447
C. Halitosis (oral malodor) 1448
D. Oral Issues Related to Aging 1450
1. Demographics of Aging: What to Expect 1450
2. Oral Health and the Aging 1451
6.18.1 Personal Oral Care 1454

A. Dentifrices 1454
1. *Regulation (Therapeutic vs. Cosmetic Benefits)* 1454
2. *Stain Removal* 1455
3. *Abrasion* 1455
4. *Ingredients* 1456
5. *Therapeutic Ingredients* 1463
6. *Non-Therapeutic Ingredients for Cosmetic Benefits* 1466
B. Mouthrinses 1466
1. *Ingredients* 1467
2. *Manufacture* 1471
3. *Packaging* 1472
6.18.2 Oral Hygiene Aids 1472
A. Manual Toothbrush 1472
1. *Historical Perspective* 1472
2. *Importance of Toothbrush Features* 1473
B. Powered Toothbrush 1474
1. *Historical Perspective* 1474
2. *Types of Powered Toothbrushes* 1475
a. Range of Products 1475
b. Action 1475
c. Sonic and Ultrasonic 1476
d. Additional Features 1476
C. Interdental Cleaning Devices 1476
1. *Importance of Interdental Cleaning* 1476
2. *Dental Floss—The Shortcomings* 1477

PART 7 SENSORY CHARACTERIZATION

PART 7.1

SENSORY SIGNALS—THE APPLIED SCIENCE OF SENSORY PERCEPTION AND ITS VALUE

Author:
Lee Stapleton
Program Director
Sensory Spectrum

TABLE OF CONTENTS:

7.1.1	Overview	1486
7.1.2	History of sensory evaluation	1487
7.1.3	Defining sensory properties	1488
7.1.4	Rationale for generating technical-based language for objective product description	1489
7.1.5	Introduction to descriptive analysis methodology	1491
7.1.6	The spectrum descriptive analysis method: philosophy and principles	1492
7.1.7	Fundamentals for developing lexicons	1493
7.1.8	Process for developing personal care product lexicons	1494
7.1.9	Sample lexicon and testing protocol for lotions and creams	1498
7.1.10	Sample protocol for skin preparation and maintenance during testing	1502
7.1.11	Sample lexicon and testing protocol for evaluation of hair tresses	1503
7.1.12	Sample lexicon and testing protocol for evaluation of lather and skinfeel of bar soaps	1508
7.1.13	Sample lexicon and testing protocol for evaluation of appearance and skinfeel of antiperspirants using inner arm site	1511
7.1.14	Sample lexicon and testing protocol for evaluation of appearance and skinfeel of facial foundation using half-face	1516
7.1.15	Applications of descriptive analysis for personal care and cosmetics	1520

PART 8 DELIVERY SYSTEMS

PART 8.1

DELIVERY SYSTEMS FOR COSMETICS AND PERSONAL CARE

Authors:
Nripen S. Sharma Ph.D., Salvona LLC ,
Bryan Grossman
Sam Shefer Ph.D.

TABLE OF CONTENTS:

8.1.1	Background and Motivation	1531
8.1.2	Classification of Delivery Systems	1533
	a. Powder Technologies	1533
	b. Improving Performance - MultiSal	1535
	c. Gel- based encapsulation systems	1537
	d. Porous polymeric systems	1538
8.1.3	Lipid-B based Encapsulation Systems	1550
	a. Liposomes	1550
	b. Solid Lipid Nanoparticles	1551
	c. Lipid-based sub-micron technology - SalSphere	1552
8.1.4	Sugar-B based Technologies	1554
	a. Cyclodextrins	1554
8.1.5	Other Delivery Systems	1559
	a. HydroSal Technology	1559
	b. Cellesence	1560
	c. Fermenich	1560
	d. Thermarome	1560
	e. Givaudan	1560
	f. Evoglass	1561
	1. Retinol	1561
	2. Menthol	1562
	3. Resveratrol	1562
	4. Benzoyl Peroxide	1562
	5. Salicylic Acid	1563
	6. Fragrances	1563
8.1.6	Technical Challenges in Delivery Systems	1563

PART 9 NUTRACOSMETICS

PART 9.1

THE USE OF NUTRACEUTICAL INGREDIENTS IN THE COSMETIC INDUSTRY

Author:
Qi Jia
Chief Science Officer
Unigen Inc. 3005 First Avenue, Seattle, WA 98121

TABLE OF CONTENTS:

9.1.1	Introduction	1568
9.1.2	Nutraceutical ingredients that are suitable for cosmetic usage	1569
9.1.3	Characterization of nutracosmetic ingredients based on biological function	1570
	a. Anti-oxidation	1570
	b. Anti-inflammation	1572
	c. Immune protection	1575
	d. Skin hydration	1576
	e. Supporting healthy skin-cell renewal and rebuilding dermal structure	1577
	f. Anti-skin aging	1577
9.1.4	Bioavailability and clinical considerations	1578
Conclusion		1579
Acknowledgement		1580

PART 9.2

MULTI-FUNCTIONAL BOTANICALS FOR NUTRICOSMETICS APPLICATIONS

Authors:
Anurag Pande, Ph.D.
Dr. Muhammed Majeed
Sabinsa

TABLE OF CONTENTS:

9.2.1	Introduction (a About the Nutricosmetics in general)	1588
9.2.2	Global market	1588
9.2.3	Ayurveda and Botanicals	1589
9.2.4	Multifunctional Nutricosmetics	1589
	a. Amla - Saberry (Indian Gooseberry)	1589
	b. Green Tea polyphenols (Green Tea)	1591
	c. Ellagic acid (Pomegranate)	1592
	d. Curcumin C3 Reduct (Turmeric)	1594
	e. Cococin (Coconut Water)	1596
Conclusion		1597

PART 10 NANOCOSMETICS

PART 10.1

NANOCOSMETICS

Authors:
Allison Kutner,
Joy Makdisi,
Adam Friedman, MD, FAAD
Division of Dermatology
Albert Einstein College of Medicine

TABLE OF CONTENTS:

	Nanotechnology and anti-aging	1602
10.1.1	Introduction	1602
10.1.2	Nanomaterials for skin delivery: nanoemulsions, liposomes, and nanoparticles	1603
	a. Nanoemulsions	1603
	b. Liposomes	1604
	c. Nanoparticles	1604
10.1.3	Nanotechnology and photoprotection	1607
10.1.4	Nanotechnology and hair care	1611
10.1.5	Nanotechnology and makeup/coverup	1613
10.1.6	Nanotechnology and emollient therapy	1615
10.1.7	Nanotechnology and anti-aging	1618
Conclusion		1622
References		1623

PART 11 TESTING

PART 11.1

METHODS TO ASSESS SKIN BARRIER INTEGRITY:
EFFECTS OF CLEANSING PRODUCTS

Authors:
Guojin Lu,
Roger L. McMullen,
David J. Moore
Ashland Specialty Ingredients

TABLE OF CONTENTS:

11.1.1 Introduction 1635
a. Skin structure and functions 1635
b. Cleansing and commonly used surfactant systems in cleansing formulations 1636
c. Skin damages by cleansing products 1637
11.1.2 Physicochemical interactions between surfactants and skin 1638
a. SC protein binding, denaturation, dissolution, and SC swelling 1639
b. SC lipid extraction and selective removal 1640
c. Disruption of SC lipid organization/structure and change of lipid composition 1641
d. pH effect 1642
11.1.3 Approaches and methods to assess the effects of cleansing stresses on skin barrier integrity 1643
a. Surfactant-skin/SC interactions 1644
1. Sensory testing and substantiating instrumental methods 1644
2. Microscope, video microscopy for skin surface topography 1645
3. Skin penetration/permeability by Franz cell and impedance measurements 1645
4. Mechanical behavior of skin 1648
5. Bioengineering methods to measure water flux and water content of skin 1649
b. Surfactant-lipid interactions 1651
1. Differential scanning calorimetry (DSC) 1651
2. Vibrational spectroscopy (FT-IR) 1651
3. Quartz crystal microbalance (QCM) 1653
c. Skin-protein interactions 1655

1. BSA denaturation test 1655
2. Zein solubility assay 1656
3. NMF level measurements 1657
Conclusion 1657
References 1658

PART 11.2

IMAGING TECHNIQUES AND ANALYSIS FOR QUANTIFICATION OF SKIN APPEARANCE

Author:
Roger L. McMullen, Ph.D.
Principal Scientist
Materials Science Department
Ashland, Inc.
Bridgewater, NJ 08807

Adjunct Professor
School of Natural Sciences
Fairleigh Dickinson University
Teaneck, NJ 07666

TABLE OF CONTENTS:

11.2.1 Skin Surface Imaging and Analysis 1673
a. Polarized Light Photography 1674
b. Imaging Techniques with Skin Replicas 1678
c. Fringe Projection Methods to Measure Skin Topography 1680
d. Pore Measurements 1684
e. Skin Thermography 1686
f. Ultraviolet (UV) Reflectance Photography 1689
g. Fluorescence Reflectance Photography 1690
h. Multi-Spectral Multi-Modal Facial Imaging 1692
i. Photographic Analysis of Lips 1694
j. Hyperpigmentation Measurements of Skin 1694
k. Imaging of Cellulite 1695
11.2.2 *In Vivo* Imaging of Internal Features of Skin 1695

a. Reflectance Confocal Microscopy 1696
b. Ultrasonography 1700
11.2.3 High-Resolution Microscopic Techniques for Imaging Skin 1703
a. Reflected Light Microscopy (Epi-illumination) 1703
b. Scanning Electron Microscopy (SEM) 1707
c. Transmission Electron Microscopy (TEM) 1709
d. Atomic Force Microscopy (AFM) 1713
11.2.4 Image Analysis to Quantify Histological and Immunofluorescent Staining of *Ex Vivo* and *In Vitro* Skin Cell Cultures 1715
a. Measuring Pigmentation of Histological Skin Sections 1716
b. Immunofluorescence Staining Quantification in Fibroblast Cell Cultures 1719
c. Image Analysis of Triple-Stained Normal Human Keratinocytes (NHKs) 1721
d. Measurement of Collagen IV Expression at the Dermal-Epidermal Junction 1723
Conclusion 1725
Acknowledgments 1725
References 1725

PART 11.3

BIOPHYSICAL MEASUREMENT AND EVALUATION OF SKIN ELASTICITY AND TOPOGRAPHY

Authors:
Stefanie Luebberding, PhD
Nils Krueger, PhD

IRosenpark Research
Wilhelminenstrae 13
64283 Darmstadt (Germany)

TABLE OF CONTENTS:

11.3.1 Skin Topography 1733
a. Quantitative assessment of skin topography 1734
b. Replica-based methods 1735
c. 3D Photogrammetry 1737
d. Fringe Projection Method 1738

11.3.2 Skin Elasticity 1741
a. Quantitative assessment of skin elasticity 1742
b. Tensile Testing 1743
c. Torsion Technique 1744
d. Impact Technique 1744
e. Elevation Technique 1745
Conclusion 1747

PART 11.4

A SURVEY OF TEST METHODOLOGY USED IN EVALUATING THE DAMAGE, PROTECTION AND REPAIR OF HAIR

Authors:
Ray Rigoletto Sr. Manager,
Global R&D Applications Care Specialties: Hair Care; Home Care
Ashland, Inc.
1005 US Hwy No. 202/206 Bridgewater, NJ 08807

Tim Gillece
Ashland, Inc.

TABLE OF CONTENTS:

11.4.1 Introduction 1756
11.4.2 The nature of hair damage 1758
11.4.3 Simulating damaging hair treatments for studying the alleviating effects of protective and repair ingredients 1761
a. Treatment schedules 1761
1. Thermal Exposure 1761
2. UV Exposure 1763
3. Color wash-fastness techniques 1764
4. Mechanical and thermal-mechanical damage 1765
11.4.4 Instrumentation and experimental methods for studying damage and protection of hair 1766
a. Physical-Chemical 1766

1. *Differential Scanning Calorimetry* 1766
2. *Surface Tension, Wetting, and Contact Angle Analysis* 1771
3. *Dynamic Vapor Sorption (DVS)* 1782
4. *Streaming Potential* 1788
5. *Time of Flight-Secondary Ion Mass Spectrometry (ToF-SIMS)* 1789
6. *X-ray Photoelectron Spectroscopy (XPS)* 1793
7. *Inverse Gas Chromatography (IGC)* 1795

b. Spectroscopic 1805
1. *Infrared Imaging (IR imaging)* 1805
2. *Spectrofluorimetry* 1809

c. Microscopy 1813
1. *Optical Microscopy* 1813
2. *Microfluorimetry* 1814
3. *Scanning Electron Microscopy (SEM)* 1817
4. *Atomic Force Microscopy (AFM)* 1820

d. Mechanical properties 1824
1. *Tensile testing* 1824
2. *Impact Loading* 1825
3. *Flexabrasion* 1826
4. *Fatigue analysis* 1826
5. *Torsional Strain* 1828
6. *Texture analysis* 1831
7. *Dynamic Mechanical Analysis (DMA)* 1834

e. Image analysis 1838
f. Infrared Thermography (IRT) 1840

11.4.5 Color protection 1843
a. Color wash-fastness of oxidative hair color from shampoo stripping 1843
1. *Colorimetry* 1844
2. *Image analysis of digital photographs* 1845

b. Color Protection from UV-Induced Fading 1847

11.4.6 Repair Techniques 1849
a. Protein Hydrolyzates 1850
b. Cuticle Decementation and its Repair 1851
c. Repair of Split Ends 1852
d. Repair of the Surface Lipid Layer 1854
e. Strategies for Permanent Mending of Hair 1855

11.4.7 Tests to study whole hair attributes from damaging effects and improvements with cosmetic treatments 1855
a. Panel testing 1856
b. Fiber fragmentation techniques 1858
c. Mechanical combing 1859
d. Salon Testing 1862

Conclusion 1863
Acknowledgments 1863

PART 11.5

CLINICAL TESTING OF COSMETICS AND SKIN CARE PRODUCTS: METHODS AND INSTRUMENTATIONS

Author:
Iqbal Sadiq, M.Phil.
Director Research and Technology
Product Investigations, Inc.
151 East Tenth Ave., Conshohocken, PA 19428, USA

TABLE OF CONTENTS:

11.5.1	Introduction	1876
11.5.2	Cosmetics and Skin Care products for human use	1879
11.5.3	Skin Strata	1879
11.5.4	Bio-Instrumentation	1882
	a. General	1882
	b. Environmental Chamber	1882
11.5.5	Skin Hydration	1883
	a. Skicon	1883
	b. Novameter	1883
	c. Corneometer	1884
	d. Sorption-Desorption Test	1884
	e. Moisture Accumulation Test	1884
11.5.6	Trans-Epidermal Water Loss	1884
	a. Evaporimeter	1885
	b. Dermalab	1885
11.5.7	Skin Blood Flow, Color, Erythema	1885
	a. Laser Doppler Flowmetry	1886
	b. Colorimetry	1886
	c. Reflectance Spectrophotometry	1887
11.5.8	Imaging Techniques	1889
	a. Digital Photography	1889
	1. Face Photography	1889
	2. Polarized Light Photography	1891
	3. Fluorescence Photography	1891
	4. Ultraviolet Light Photography	1891
	b. Ultrasound	1891
	c. Videomicroscopy	1892
	d. Confocal Microscopy	1893

	e. Optical Coherence Tomography (OCT)	1895
11.5.9	Skin Topography	1896
	a. Replica of Skin	1896
	b. Phase Shift Fringe Projection Device	1897
	c. Calculation of Roughness Values	1898
	d. Surface Area Calculation	1899
11.5.10	Viscoelastic Measurements	1899
	a. Suction Device	1899
	b. Ballistometry	1901
	c. Torsional Ballistometry	1901
11.5.11	Some Ex Vivo Techniques	1902
	a. Desquammation Measurement	1902
	b. Cyanoacrylate Surface Biopsy	1903
	c. Sebum Collection Assay	1903
11.5.12	Application of Bio-Instrumentation: Some Examples	1904
Conclusion		1923

PART 12 SUSTAINABILITY AND ECO-RESPONSIBILITY

PART 12.0

A GLOBAL APPROACH FOR THE COSMETIC AND PERSONAL CARE INDUSTRY 1990

Editor's Overview
Alban Muller (President, Alban Muller Group)

PART 12.1

DEFINING SUSTAINABILITY AND HOW IT CHANGES THE INNOVATION PROCESS

Authors:
Jamie Pero Parker (Innovation Manager, RTI International) and
Phil Watson (Technology Commercialization Manager, RTI International)

TABLE OF CONTENTS

12.1.1 Sustainability—a critical business issue 1997
12.1.2 Innovation is a critical but challenging component of any sustainability strategy 1998
a. The concept of open innovation (OI) 1999
b. Open innovation and sustainability are synergistic 2000
c. Transparency 2000
d. Collaboration 2000
12.1.3 Integration of sustainability principles into innovation practices is evolutionary 2001
a. Six key traits of sustainable companies 2003
b. Few companies explicitly recognize and exploit open innovation as a tool to help them on this sustainability pathway 2004
c. Companies practice open innovation for sustainability adopt a more complete model of open innovation 2005
d. Practical lessons can be learned from companies that have recognized the synergies between sustainability and OI 2006
References 2007

PART 12.2

A BOTANIST'S VIEW OF SUSTAINABILITY: USE OR ABUSE IN THE PERSONAL CARE INDUSTRY?

Author:
Michael J. Balick (Vice President of Botanical Sciences, Director of the Institute of Economic Botany, New York Botanical Gardens)

TABLE OF CONTENTS

12.2.1 Introduction 2009
12.2.2 What happens once you find a species of interest? 2011
1. Accurate identification of botanicals 2011
2. Understanding why the plant is used in the product, and what part or form will give the best result to the consumer 2011
3. Truthful representation of the local uses of the plant in marketing efforts 2011
4. Making sure the environment is not degraded as a result of harvesting botanicals 2012

5. Ensuring that local communities are not negatively impacted by the harvest of the plant 2012
6. Under the spirit and intent of the United Nations–sponsored Convention on Biodiversity, compensation to groups and source countries where the materials and ideas were obtained 2012
12.2.3 Sustainable production of wild-harvested products 2012
Acknowledgments 2016
References 2016

PART 12.3

THE HERBORETUM NETWORK FOR PROMOTING LOCAL CULTURES AND BIODIVERSITY

Author:
Genevive Bridenne (CIO, Alban Muller Group)

TABLE OF CONTENTS

12.3.1 Introduction 2018
12.3.2 The Herboretum, a true open-air plant laboratory dedicated to plants used in beauty, health, and well-being 2019
a. An area of reflection, a scientific and natural approach 2019
b. An area of protection, a long-term commitment to the protection of plant resources 2022
12.3.3 The Herboretum organizes themed visits of four different kinds: school groups, the general public, professionals, and organizations 2025
12.3.4 The Herboretum Network, a unique interface between the phytocosmetic industry and biodiversity 2026
Conclusion 2027

PART 12.4

THE ADVANTAGES AND POTENTIAL CONTRIBUTION OF LOCAL CULTURES FOR CARBON FOOTPRINT REDUCTION

Author:
Jean-Marc Seigneuret (Technical Director, Alban Muller Group)

TABLE OF CONTENTS

12.4.1	Introduction	2029
12.4.2	The use of plants in cosmetics	2030
12.4.3	Plant origin	2032
	a. Name and identification	2032
	b. Wild plants	2033
	c. Cultivated plants	2034
	d. Good agricultural practices	2035
12.4.4	Plant breeding	2036
	a. Mass selection	2036

INGREDIENTS I

INGREDIENTS

Editor's Introduction to the Ingredient Section

By

Chia Wen Chen
Executive Director of Basic Research—BioActives
Estée Lauder Companies

125 Pinelawn Road
Melville, NY 11747

When Meyer approached me in July 2012 to be the Editor for the ingredient section of the 9th edition of *Harry's Cosmeticology*, I gladly accepted, not knowing how much work would be involved. How naïve of me.

It's been about ten years since the last (8th) edition, and we would point out that *Harry's* has been the largest-selling book to our industry over the past 50 years. In the last decade or so, there have been a number of key breakthroughs in ingredient development, and this section is a perfect place to introduce them. We have chosen to divide up the ingredients that have been widely employed or are relatively new, but promising enough that we have included them. You will find three Parts to our ingredient description. After a while, between Meyer and me, the number of authors and subjects somehow multiplied and the entirety just became "ours" and yours!

A few breakthrough technologies that are worth highlighting include: from land to laboratory (the use of biotech/fermentation to produce ingredients); plant stem cell technology; development and utilization of marine ingredients; breakthroughs in skin whitening; and the advancement in hyaluronic acid.

We started calling on friends in the industry to join us and help. We took this opportunity to put together a program as complete as possible to include ingredients from ingestible to topical, sea to land, and rare to sustainable (land to laboratory). In terms of functionalities, we have covered the various aspects of skin concerns to prevent aging—a major area to come as a result of the rapidly escalating population of seniors and their need, nay demand, for products to make them look younger and address their hope that some of these could actually make their skin behave as if it was younger.

Thanks to all the contributing authors, we finally pulled the whole program together and after 18 months of reading, editing, and revising (the scenery in my backyard went from luscious green to snow twice). It is finally ready for publication. Here we are: *Harry's Cosmeticology*, the 9th edition.

I was very fortunate to work with experts in the cosmetic industry who have devoted their lives to the profession (with 40+, 50+ years of experience). Editing the ingredient section is like taking abbreviated courses for a master's degree in Cosmetic Ingredients. Not only did I have the privilege to work with experts who specialize in certain types of ingredients I knew about, but I also worked with experts outside my field of training: preservation system, color, emulsifier/surfactant, and even dietary supplements.

My grateful thanks to all the authors who have graciously contributed to the ingredient section by putting their knowledge down on paper for those of you seeking such information in depth, but also for having to deal with the many edits and questions we both had as you taught us. Meyer and I believe that if you could teach us what you know, in the Harry's way—from the "simple" to the "complex"—that would indeed be a breakthrough. Our contributors have become my teachers, and hopefully lifetime friends. The ingredient section will serve as a summary and reminder for those of us working in related fields, and as a treasure for those of us unfamiliar with the topics. This section contains not only a basic know-how, but our vision is that it will also serve as a pathway to addressing accelerating skin concerns related to aging.

With the wealth of knowledge collected/found in this new edition, I can proudly say that *Harry's Cosmeticology*, 9th edition, is definitely more than a compendium or guide. I would like to thank all the contributing authors who worked with Meyer and me amidst their busy schedules—and my apologies for the harassing phone calls and emails. A special thanks to Meyer, who co-orchestrated this program with me to make this section possible. We hope the reader will enjoy the fruit of our labor as much as we enjoyed putting the ingredient section together.

SURFACTANTS: THOUGHTFUL, PRO-ACTIVE INTERVENTION AT THE INTERFACE OF MULTIPHASE DISPERSED SYSTEMS

Author

J. Mark Chandler
President of ACT Solutions Corp
www.ACTSolutionsCorp.com

ABSTRACT

Often we are asked to dig deeper and not simply look for superficial answers to life's problems. While this is generally good advice, for the formulating cosmetic chemist, this is not always the best advice. For these creative specialists the answers lay on the surface and in the surface-active agents (surfactants) necessarily employed in most cosmetic and personal care products. Without surfactants, there is no cosmetic industry. We would be left with smearing oils and colors on our bodies, and relying on water alone to clean us up. What a mess!

Surfactants are not only the key to cleansing hair and skin, but are of paramount importance in producing the desired and required aesthetics of formulations of all types and in all categories. Personal care products provide an important function for acceptance in our culture in terms of achieving a person's cleanliness and perception of beauty. These functions are crucial elements of the role of personal care products in society, but there is much more. A cosmetic product, whether it be a shampoo, skin cream, or antiperspirant, is a luxury item. Luxury items are about an experience as much as, if not more so than, an effect. In order to be successful, a personal care item must not only function, it must excite! In view of this elemental truth, proper understanding and use of these small but powerful interfacial components is a key to the commercial success of a formulation.

Understanding all of the physical/chemical aspects of surfactants is not critical to successful use of these materials. However, a background and understanding of these aspects are interesting nonetheless, and can help unlock some of the mysteries of their impact and activity on product development approaches. This chapter will first provide an introduction to the world of surfactants, and then move quick-

ly into the specific functions that surfactants perform in key application areas. Following this, a step back will be taken to look at a more detailed description of the physical/chemical aspects of how surfactants work. The chapter will conclude with a more in-depth view of the chemistry of the more important surfactants in use today and provide a glimpse into their future in the personal care industry.

4.1.10 SURFACTANT INTRODUCTION

a. History

Surfactants have been used for several millennia. Early mention of the use of soap, a naturally derived anionic surfactant, comes from the Akkadians around 2800 BCE. This surfactant was manufactured by boiling fats with ashes, and used for cleaning wool and cotton in textile production. Other early applications employed by Mesopotamians for soap was cooking utensil cleaning and treatment of skin diseases. Later the Phoenicians spread this surfactant-producing technology to Egypt and later to Gaul (today France). With the Roman conquest of Gaul, soap production became very important for use in the elaborate public baths. A full-scale soap-production facility (though no reliable production data exist) located in Pompeii was unearthed, dating back to the volcanic eruption that destroyed the city in 79 CE. Location of the facility was likely due to the ready availability of the raw material, ash, and the fact that Pompeii was a resort city.

With the fall of the Roman Empire, soap production appeared to fall considerably until around the tenth century. Not only were they the Dark Ages, they were also dirty. Soap was an item of commerce and trade, produced best by those in Italy and France, and sold around the world, though only the wealthy could afford this luxury item. In other areas, soap-making was a local or home craft. By the 17th century, many large towns had soap-boiling operations, and by 1850, commercial soap-making for the masses was established by such companies as Colgate (1).

The first nonionic surfactants came onto the scene in the 1930s, developed by the Atlas Powder Company in Delaware. Using waste sorbitol made as a by-product of mannitol production and reacting with long-chain fatty acids, the sorbitan ester surfactants were produced. In the 1940s, these oil-soluble materials were made more hydrophilic by the binding of a polyethylene oxide chain onto the molecule. For instruction on how to use these novel surfactants, which have a character much different than soap, William C. Griffin designed the HLB system. Since then, hoards of new anionic, amphoteric, and cationic surfactants have been invented and put into wide-scale use, making for a cleaner, safer, and more pleasant world.

b. General Function

The word "surfactant" is a shortening of the term "surface active agent." Surfactants' work is done at interfaces. The molecules are called amphiphilic, because they are attracted to two different characters of materials. Most often, one part of the molecule is hydrophilic, or water-loving. This portion is also call the polar head group. The other portion of this amphiphilic molecule is hydrophobic, meaning that it is uncomfortable in water. These surfactants break down the interfacial tension

between substances, one of them usually being water, and the other air, immiscible liquids, or solids. The ability of surfactants to have a dual affinity makes them uniquely placed to perform a variety of useful functions in personal care products.

c. Use

Creams and lotions are not formed or stabilized easily without the use of surfactants. Cleansing hair, face, and body is extremely difficult without the use of surfactants. Hair conditioners, makeup, and deodorants would be in a sad state without surfactants. It must be remembered that personal care items are much more than just technical items designed for a specific function on the skin or hair. All of these products are as much about the emotional experience as about the specific task. Thus personal care items are luxury goods, not unlike cars and electronics, regardless of price point. Who would buy (well, at least more than once) a lotion that stayed separated, a cream that felt terrible, or a shampoo that did not foam? All of these products could do the job technically, but would leave the consumer dissatisfied and looking elsewhere. A great many of the positive emotional cues we receive from use of our personal care products, whether they be performance or aesthetic, are the result of clever use of surfactants.

d. Types

There are hundreds of different surfactant chemistries from which to choose for a given personal care application. All of them fall into four basic categories, based on charge behavior (no, not how much the suppliers charge for these wonderful materials!). The original surfactants, soaps, belong to the greater category of anionic surfactants. These surfactants possess a net negative charge. The second group, mentioned in the History section, fall into the category of nonionic surfactants. These molecules have no charge, except when being purchased. A third group is called cationic, for they have a net positive charge. The last group is termed amphoteric, meaning the surfactant changes charge character based on the pH of the system (2).

4.1.11 FUNCTIONS

a. Emulsifying

This is likely the most complex of the surfactant functions. Recent research indicates strongly that the selection of emulsifier and emulsion stabilizer is of great importance to the overall aesthetics of a cream or lotion. Much work is involved in formulating an emulsion. Surfactants play a key role in the two main steps involved making these high value systems for the face, hand, and body. First, there is the step of droplet creation. This can be accomplished with mechanical energy

such as mixing, but aided greatly through the judicious use of surfactants, which reduce the interfacial tension between the immiscible oils and water. The second step is to stabilize these droplets against aggregation, creaming or sedimentation, Ostwald ripening, and coalescence. Density differences between phases and Van der Waals forces tend to work against these kinetically stable but thermodynamically unstable systems.

There are four main stabilization mechanisms used to produce personal care emulsions. The first is charge, or ionic stabilization. The second is nonionic, or steric stabilization. A third is stabilization based on the formation of liquid crystalline lamellar phases, and the last but not least is polymeric stabilization. Each places different demands on surfactants, and requires different formulation and manufacturing techniques. Each has advantages and disadvantages, and is seldom used in isolation.

With charge stabilization, an ionic double layer is formed around the emulsion droplet. This creates electrical repulsion with surrounding droplets, slowing emulsion instability. This can be accomplished with anionic surfactants like soaps or phosphate esters, or, less commonly, with cationic surfactants. This mechanism is almost exclusively used in oil-in-water emulsions. Very often charge stabilization is used along with steric, polymeric, and liquid crystalline stabilization. Soaps are generally formed during the formulation process through the neutralization of such long-chain fatty acids as stearic acid with sodium hydroxide or TEA. The pH of soap-stabilized systems must be above 7, which makes them irrelevant for emulsions containing alpha or beta hydroxyl acids. Phosphate esters and cationics have greater pH tolerance. As a general rule, cationic and anionic surfactants have the highest irritation potential when compared to other surfactant types, but low-irritation skin care emulsions can be formulated with judicious use of these materials.

Using nonionic emulsifiers to engineer steric stabilization of droplets requires the most formulation work to optimize, but these emulsions are generally best able to withstand the harshest formulation challenges placed on them. These challenges include low and high pH, high electrolyte levels, low and high internal phases, varying oil polarities, and combinations thereof. These emulsions must be designed such that there is a very consistent and flexible film of emulsifier around the droplets. The simple HLB system was designed to ensure maximum packing of emulsifier through tuning the ratio of hydrophilic to lipophilic surfactant based on the specific requirement of the oil phase selected.

Surfactants consist partly of the molecule that is hydrophilic, or water loving, and partly of the molecule that is hydrophobic. An HLB value is assigned to nonionic surfactants based on the weight percentage of the molecule that is hydrophilic, then dividing that number by five. For instance, a surfactant such as

Steareth-20 has a hydrophilic polar head group that is 75% of the weight of the total molecule, and the HLB value is deemed to be 15 (75 / 5 = 15). The higher the HLB, the more hydrophilic the surfactant is. Sometimes ionic surfactants are listed with HLB values, but these are of limited usefulness. Surfactants can be combined to give a composite HLB value for the system. The result is purely arithmetic. If an HLB 15 surfactant is combined with another at HLB 5, blended in equal parts, the composite HLB is 10.

Oils to be emulsified have HLB requirements. A simple test will show the required HLB of a given oil or blend of oils. Test blends of surfactants at defined HLB values are prepared, generally using sorbitan oleate (HLB 4.3) and polysorbate 80 (HLB 14.9) blended to even HLB values from 6 through 14. Two grams of each blend are mixed with 20 grams of test oil in a 50 mL glass jar with a top. Water is then added, filling each jar. The jars are capped and hand-shaken 20 times. The emulsion showing the least separation is the winner and recorded as the HLB requirement of the oil. If two of the even HLB blends appear close in stability, the odd-numbered value in between is tested.

Blends of oils have an HLB requirement equal to the sum of the HLB requirements of each oil multiplied by its percentage of the total oil phase. Once the HLB requirement for the oil phase is determined, various chemistries of nonionic surfactants can be evaluated for compatibility, cost, and effectiveness, with the optimum blend ratio already having been determined. For best emulsion stability, a blend of low and high HLB surfactants, each a few HLB units away from the requirement of the oil phase, is preferred.

The HLB system is designed for optimization of steric stabilization using nonionic emulsifiers. Other stabilization mechanisms can be used in addition to enhance emulsion stability. The system works independently of phase/volume ratio, total surfactant level, or chemistry type of ingredients.

Liquid crystalline lamellar phases are surfactant structures built in the aqueous phase either alone or around an emulsion droplet. They are generally made with nonionic surfactants, though some anionic and cationic surfactants have shown useful behavior as well. The structures formed are similar to the lipid bilayers found in the upper layers of the skin, and the surfactants used tend to have low potential for disruption of the skin moisture barrier. The resultant emulsions are reported to possess good resistance to wash-off, and offer enhanced moisturization, reduced evaporation rates, and superior delivery of water-soluble actives. Commercial examples of liquid crystal emulsifiers such as a blend of sorbitan stearate and sorbityl laurate are best utilized by adding the solid product, and any other waxy materials to be used in the formulation, to water heated to 80°C and stirring until a white uniform mixture is obtained. Heat is removed at this point with

stirring continued. A room-temperature oil phase can be added now or at any time during the cooling phase of the aqueous portion. These systems work independently of HLB, so no adjustment to the surfactant system needs to be made to account for the character of the oil phase. Small amounts of hydrocolloid should be added to enhance stability, though no additional surfactants should be used.

Surfactants are often used to help with the creation of droplets in systems that are stabilized primarily with polymers. Polymers stabilize emulsions mainly through building viscosity and a polymer matrix between the droplets of an oil-in-water emulsion. Most water-soluble polymers used to stabilize emulsions are not very interfacially active, even those that are hydrophobically modified, so as such can use the help of surfactants to reduce the amount of mixing energy necessary to create droplets, and can be further aided by the steric stabilization they provide. Generally nonionic surfactants of low to mid HLB are best. Polymers stabilize by building the rest, or zero shear viscosity of an emulsion, and allowing that viscosity to be reduced when shear is applied. These emulsions possess unique rheological and aesthetic qualities that have appeal for some applications. Polymers are very widely used to increase high-temperature stability of anionic, nonionic, and liquid crystalline stabilized emulsions.

b. Cleaning

In practice, cleaning involves wetting the soiled substrate, in case of hair or skin, removing the soil (oils, dirt, makeup) from the substrate, and suspending the soil and preventing its redeposition. Surfactants placed in water are uniquely qualified for this task. Soils are adhered to the substrate, so for good cleansing, the aqueous solution must have a greater tendency to wet the substrate than the soil. Surfactants make water wetter, in a sense. A surfactant will increase the affinity of the soil for the water. With surfactant, hydrophobic tails attached to the soil and polar head group out into the water, and the soil moves to maximize surface contact with the water. Surface area is maximized by the soil being lifted from the substrate and forming emulsion droplets. Anionic and nonionic surfactants are often blended for superior cleansing.

c. Foaming

Foam is a dispersion of gas in a small volume of liquid. The ability of a surfactant to stabilize foam depends on the ability to increase elasticity at the gas-liquid interface. Anionic surfactants generally provide the highest foam because the ionic charges and oxygen-containing functional groups help increase elasticity. Eventually, though, film drainage is too great and foams break by what is termed the Marangoni Effect.

Foam does not have a physical role in cleansing, but it is an important cue to the consumer that a shampoo or other cleanser is working. More importantly, large volumes of tight, rich, long-lasting lather are a sign of luxury to the consumer and greatly enhance the experience and chance of repurchase (3).

d. Solubilization

In the IUPAC Compendium of Chemical Terminology, micellar solubilization is defined as follows: "In a system formed by a solvent, an association colloid and at least one other component (the solubilizate), the incorporation of this other component into or on the micelles is called micellar solubilization, or briefly, solubiliztion." The term "solubilizer" has, in many parts, come to be synonymous with solvent. This causes great confusion and should be avoided. In a sense, though, such materials as water-insoluble fragrance oils dissolve in the clear micelle solution of cleanser surfactant systems. Nonionic surfactants are, by far, the best solubilizers, and are often added to anionic surfactant systems for this purpose.

Just as foam has no technical value in the cleansing process, neither does fragrance. Nonetheless, the scent of a shampoo or body wash may be the determining factor in deciding consumer acceptance and delight. Having the fragrance properly solubilized in a clear shampoo or skin cleanser is extremely important.

e. Conditioning

Hair and skin possess a net negatively charged surface. These substrates are conditioned through the use of positively charged cationic surfactants, which attach to the oppositely charged hair or skin. Hair conditioners use long-alkyl-chain cationic surfactants, which ease brushing and improve the overall appearance of the hair. Conditioning shampoos use cationic polymers, which are deposited on to the hair upon rinsing, often aided in this process by the use of nonionic surfactants in addition to the base-anionic surfactant system.

f. Dispersing

Dispersants are generally used to improve the appearance and performance of liquid foundation makeup and sunscreens containing inorganic particles. Low HLB nonionic surfactants are used to disperse solids in emollient oils. The dispersant must be able to attach to the particular particle surface or coating, and also be soluble in the dispersing media. Once the optimum dispersant has been selected, a dispersant demand study should be performed to determine the optimum level of dispersant. The optimum level will yield the lowest viscosity for the dispersion, with lower and higher levels of dispersant showing increased viscosity.

g. Lubricating

Surfactants can have a lubricating effect on the hair and skin. The surfactants as such, especially cationic surfactants, possess a lubricating effect, though this is effect is also seen in such anionic surfactants as phosphate esters. Other surfactants, especially in certain association structures, can have a lubricating effect.

4.1.12 APPLICATIONS: A LOOK AT SOME OF THE MANY

a. Creams and lotions

Surfactants are mainly used as emulsifiers in creams and lotions. Emulsifiers not only allow the emollient oils to peacefully coexist, but also have an impact on the aesthetics of an emulsion. Use levels are generally from 1% to 5%, and generally are anionic or nonionic, though cationics are used as well. Irritation potential can be a concern, as well as disruption of the skin barrier lipid bilayers, especially when using more hydrophilic surfactants. Soaps and phosphate esters are the primary anionic surfactants employed. Sorbitan esters, polysorbates, glyceryl esters, sucrose esters, PEG-esters, and ethoxylated fatty alcohols are the most popular nonionics.

b. Shampoos

Surfactants perform the cleansing and foaming of shampoos. In addition, the viscosity and flow characteristics are dictated by the selection and interaction of the surfactants. Shampoos generally start with an anionic sulfate surfactant for maximum foaming and cleansing, add an amphoteric or betaine surfactant to increase mildness and give mild conditioning, and follow with a nonionic amide for viscosity and flow improvements, fragrance solubilization, and foam enhancement. To these systems salt is added to increase viscosity. The anionic portion is generally from 6% to 12%, the amphoteric roughly 5%, and the nonionic around 2% of the formulation. Sulfate-free formulation brings on a host of challenges in terms of cost, viscosity, flow, clarity, and foam.

c. Skin Cleansers

Skin cleanser formulation is very similar to that for shampoos. Many times it is difficult to distinguish a shampoo ingredient list from that of a skin cleanser. Handwash formulations tend to use anionic sulfonates as well as sulfonates. Cost is generally lower, as is foam and viscosity. Facial cleansers tend to use milder anionic surfactants and higher levels of amphoteric and nonionic surfactants. Body washes very often take on an additional responsibility of skin moisturization, containing relatively high levels of emollients.

d. Conditioners

Most hair conditioners are built with a long-alkyl-chain cationic surfactant for conditioning, a fatty alcohol for viscosity, and a nonionic ethoxylated fatty alcohol for emulsion stability. These systems usually have less than 10% total solids, often more like 5%.

e. Color Cosmetics

Surfactants are used as emulsifiers and dispersants in such color cosmetics applications as liquid foundations and mascara. Many foundation makeup formulations are water-in-silicone emulsions, and as such use silicone-based nonionic emulsifiers.

f. Antiperspirants

Surfactants are not an integral element of stick antiperspirant formulations, but are at times used to enhance the washability of formulations from the skin and fabrics. Roll-on antiperspirants are a very difficult emulsion challenge, because they generally are of low viscosity, low pH, very high electrolyte content, low internal phase, and contain polar oils and fragrances. Blends of low and high HLB nonionic ethoxylated fatty alcohols are most widely used for this application.

4.1.13 HOW SURFACTANTS WORK

a. Surface tension effects

Surfactants lower the surface tension of water by reducing the energy at the air/water interface. This surface tension reduction allows water to better wet surfaces for effective cleansing action. The concentration of surfactants is higher at the surface than in solution.

b. Interfacial activity

There is considerable interfacial tension between water and oils, causing them not to mix. Strong hydrogen bonding forces keep water molecules isolated from the less polar oils. Surfactants work at the interface of oils and water due to their amphiphilic nature. Hydrophobic portions of surfactants associate with the oils while the polar head groups interact with the water, lowering the tension at the interface. Interfacial activity of surfactants is also involved in the cleansing mechanism as soils are emulsified and removed in the water. Emulsification is truly an interfacial phenomenon.

c. Micelles

Micelles are simple surfactant structures formed in aqueous solutions. When in water, surfactants will move to protect the hydrophobic tails by collecting in spherical

structures with those tails on the inside of the sphere. The surfactant concentration at which these structures begin to form is called the Critical Micelle Concentration (CMC). Solubilization takes place as oil is dissolved in the interior of the micelle.

d. Aggregation structures

Various surfactants at varying concentrations will form more advanced structures in water. As surfactant concentrations increase in water, cubic then hexagonal phases (and some lamellar) are formed. These phases are often seen in anionic cleansing surfactant systems and can be altered by the incorporation of amphoteric and nonionic surfactants to the mix, and the addition of salts (4). The viscosity produced by the manipulation of these variables can be considerable, and the resultant shear thinning rheology quite pleasing to the consumer. Lamellar phase liquid crystals formed by certain lipophilic surfactant emulsifiers, when heated above the Krafft temperature in water, are very useful in the development of creams and lotions with exciting aesthetic and performance attributes.

e. Charge effects

Surfactants carry various electrical charges in water. Those with a net negative charge on the polar head group are called anionic, and those with a net positive charge are referred to as cationic. The charge can be fairly localized or dispersed, changed by such materials as electrolytes or other surfactants (4). Nonionic surfactants possess no appreciable electrical charge. Structures surrounded by a certain charge will be repulsed by adjacent structures carrying the same charge. Amphoteric, or zwitterionic surfactants vary their charge behavior based on the pH of the system. At lower pH, these surfactants exhibit cationic behavior; in more alkaline situations, anionic. In addition, there is a narrow pH range in which amphoteric surfactants show nonionic surfactant character known as the zwitterionic point. Care should be taken when using amphoteric surfactants not to formulate at the zwitterionic point for a given material.

f. Foam generation

Foam is generated when air is trapped beneath a liquid surface containing surfactant molecules. The physical action of rubbing a surfactant solution on to the hair or body with the hands helps create the pockets of air. Anionic surfactant solutions create the greatest volume of foam. When amphoterics are used as primary surfactants, the foaming character is not great, but when combined with anionics the effect is quite good with regard to foam generation. Nonionic surfactants do not create large amounts of foam, though some can give an acceptable amount of foaming, even if the quality of the foam is not outstanding.

g. Foam stabilization

The various pressures exerted on a foam structure eventually cause it to be destroyed. When draining of the liquid causes the top wall of the foam to fall below a critical thickness, the bubbles break. Foams created with anionic and amphoteric surfactants are stabilized through the use of such nonionic surfactants as alkanolamides. Complex mixtures of surfactants allow for the generation of initial, or flash foam, large volumes of foam, and foam that lasts through the use of the product on the hair, hands, face, and body.

4.1.14 SURFACTANT CHEMISTRY

a. Anionics

Anionic surfactants possess a net negative charge (5). Primary use of anionic surfactants is for foaming and cleansing in cleanser systems. In addition, anionics are used as emulsifiers in creams and lotions. Of surfactants used in personal care products, anionics are used in the largest volumes. Skin and eye irritation potential can be high, but usually mitigated by low use levels and being combined with other surfactants.

Sulfates

The primary use of sulfates is in shampoos and body washes. Foaming capabilities are outstanding. Sulfates are produced by the sulfation of natural or synthetic alcohols or alcohol ethoxylates. Counter ions are typically sodium or ammonium. Ethoxylation of the alcohol decreases irritation and foam. Structure forned is $ROSO_2^-$ in which R is a fatty alcohol or alcohol ethoxylate.

Typical sulfates used include:

1. Sodium lauryl sulfate
2. Sodium laureth sulfate
3. Ammonium laureth sulfate
4. Sodium trideceth sulfate

Sulfonates

Sulfonates are used mainly in hand wash formulations and are manufactured by sulfonation of alpha olephins. Foaming capabilities are very good and the surfactant is stable over a wide pH range, though formulations can be difficult to build in viscosity. Chemical structure formed is RSO_2^- where R is an alpha olefin.

Typical sulfonates used include:

(1) Sodium C14-16 olefin sulfonate

Phosphate esters

Phosphate ester surfactants are used as emulsifiers in creams and lotions, especially sunscreens, and foamers in facial cleansing systems. They are produced

through phosphation of alcohols or alcohol ethoxyates. Emulsions are stable over a wider pH range than soap-emulsified systems. Phosphate esters produce thick, rich, lubricious foams in cleansers. Chemical structure is $ROPO(OH)O^-$ where R is a natural or synthetic alcohol or ethoxylate.

Typical phosphate esters used include:

(1) Sodium laureth-4 phosphate
(2) Potassium C12-13 alkyl phosphate
(3) Potassium cetyl phosphate (emulsifier)
(4) Dicetyl phosphate (and) Ceteth-10 phosphate (emulsifier)

Sarcosinates

Sarcosinate surfactants are used mainly in mild foaming cleansers. Foams produced are thick and rich, and are under consideration as primary foaming surfactants. They offer conditioning effects and are compatible with cationic surfactants. Production is through reaction of an acyl chloride with n-methyl glycine.

Typical sarcosinates used include:

(1) Disodium laureth sulfosuccinate
(2) Disodium lauryl sulfosuccinate

Glutamates

Glutamates are very mild surfactants used in skin-cleansing systems. They form thick foams and offer excellent feeling on the skin after rinsing. Glutamates are compatible with cationics and are considered acceptable for many natural formulations.

Typical glutamates used include:

(1) Sodium cocoyl glutamate
(2) Disodium lauroyl glutamate

Lactylates

Lactylate surfactants are used as emulsifiers in creams and lotions and as foam boosters and stabilizers in shampoos and skin cleansers, imparting softness and moisturization. In cleansers, lactylates can improve the salt-thickening response of cleansing surfactant systems. They are the reaction product of a fatty acid and lactic acid. Lactylates are seen as naturally derived.

Typical lactylates used include:

(1) Sodium lauroyl lactylate
(2) Sodium stearoyl lactylate (emulsifier)

Isethionates

Isethionates are mild surfactants used primarily in synthetic detergent cleansing bars, but are finding use in liquid cleansing products. Foam is slippery and

luxurious, and are the esters of isethionic acid and fatty acids. The methyl ester can be used in clear systems.

Typical isethionates used include:

(1) Sodium cocoyl isethionate
(2) Sodium methyl lauroyl isethionate

Taurates

Taurates are mild surfactants used in opaque shampoos and skin cleansers. They offer foam boosting and stabilization with light conditioning properties.

Typical taurates used include:

(1) Sodium methyl cocoyl taurate

Carboxylates

Carboxylate surfactants are mild and used to reduce the eye irritation of anionic surfactants. Chemical structure is $RCOO^-$ where R is an alcohol or, more typically, and ethoxyate.

Typical carboxylates used include:

(1) Sodium trideceth-7 carboxylate

Other anionic surfactants

Other anionic surfactant classes of note include:

(1) Alpha sulfo methyl esters
Sodium methyl 2-sulfolaurate (and) disodium 2-sulfolaurate
(2) Fluorosurfactants
TEA-C8-18 perfluoroalkylethyl phosphate
(3) Sulfosuccinates
Disodium laureth sulfosuccinate
(4) Sulfoacetates
Sodium lauryl sulfoacetate
(5) Secondary alkane sulfonates
Sodium C14-17 alkyl sec sulfonate

b. Nonionics

Alkanolamides and alkoxylated amides

Alkanolamides and alkoxylated amides are used extensively in all types of cleanser formulations. These materials help manage salt thickening, solubilize fragrances, modify foam feel and density, and enhance conditioning. Alkanolamides are generally produced through the reaction of a fatty triglyceride with such amines as monoethanolamine (MEA) and diethanolamine (DEA), though the latter have fallen into disfavor based on toxicological concerns. Alkoxylated amides generally

are produced by the addition of propylene oxide or ethylene oxide to an MEA amide to transform the solid amide into an easier-to-use liquid.

Typical alkanolamides and alkoxylated amides used include:
(1) Cocamide MEA
(2) Cocamide DEA
(3) PPG-2 hydroxyethyl cocamide
(4) PEG-5 cocamide

Ethoxylated fatty alcohols

Ethoxylated fatty alcohols are used primarily as emulsifiers in creams and lotions, roll-on antiperspirants, and hair conditioners, colors, and relaxers. In addition, certain ethoxylated fatty alcohols are used as solubilizers and gelling agents in hair-styling products. There are low and high HLB variants based on the fatty chain length and degree of ethoxylation.

Typical ethoxylated fatty alcohols used include:
(1) Steareth-2
(2) Steareth-21
(3) Laureth-23
(4) Isoceteth-20

Glyceryl and polyglyeryl esters

Glyceryl and polyglyceryl esters are used as emulsifiers in creams and lotions. Glyceryl esters are produced generally through transesterification of a triglyceride and glycerin. Polyglyceryl esters are reaction products of a fatty acid and a polymerized glycerin. Glyceryl esters are low HLB emulsifiers, often used along with PEG-esters. Low HLB polyglyceryl esters are very effective water-in-oil emulsifiers, whereas the higher HLB products can help form ethoxylate-free steric stabilized emulsions.

Typical glyceryl and polyglyceryl esters used include:
(1) Glyceryl stearate
(2) Polyglyceryl-3 diisostearate
(3) Polyglyceryl-10 oleate

PEG-esters

PEG-esters are used primarily as emulsifiers in creams and lotions. They are produced either through reaction of a fatty acid with ethylene oxide or polyethylene glycol. PEG-esters are normally high HLB emulsifiers, though specialized polymeric PEG-esters are powerful water-in-oil emulsifiers.

Typical PEG-esters used include:
(1) PEG-100 stearate
(2) PEG-40 stearate
(3) PEG-30 dipolyhydroxystearate

Silicone copolyols

Silicone copolyols are powerful water-in-silicone and water-in-oil emulsifiers used in liquid foundations, sunscreens, and facial treatment products. Ethylene oxide and often propylene oxide are added to the dimethicone.

Typical silicone copolyols used include:

(1) PEG/PPG-18/18 dimethicone
(2) Lauryl PEG/PPG-18/18 methicone
(3) Cetyl PEG/PPG-10/1 dimethicone

Alkyl polyglucosides

Alkyl polyglucosides are used as foamers and irritation reducers in mild cleansing formulations. More recently, longer chains are being marketed as liquid crystal emulsifiers for creams and lotions. They are formed through the reaction of a fatty alcohol with glucose. Alkyl polyglucosides are seen as naturally derived alternatives to ethoxylated nonionic surfactants.

Typical alkyl polygucosides used include:

(1) Decyl glucoside
(2) Lauryl glucoside
(3) Cetearyl glucoside

Polysorbates

Polysorbates are used in baby shampoos to reduce eye irritation and sting, and in creams and lotions as high HLB emulsifiers. In addition, they are used as solubilizers in gels, toners, and cleansers. Polysorbates are produced by the reaction of sorbitan esters with ethylene oxide.

Typical polysorbates used include:

(1) PEG-80 sorbitan laurate
(2) Polysorbate 20
(3) Polysorbate 60
(4) Polysorbate 80

Sorbitan esters

Sorbitan esters are used mainly as emulsifiers in creams and lotions. They are the reaction product of sorbitol and various fatty acids. Sorbitan esters are used as low HLB emulsifiers for steric stabilization and also can form liquid crystalline structures. Oleate esters are also used to produce water-in-oil emulsions.

Typical sorbitan esters used include:

(1) Sorbitan stearate
(2) Sorbitan sesquioleate

Poloxamers

These ABA type block copolymers are mainly used as solubilizers and gelling agents in oral care products. The A portion of the block is an ethylene oxide polymer, the B in the center is a propylene oxide polymer serving as the hydrophobic portion. Each block is varied to obtain differing degrees of hydrophilicity and phase behavior.

Typical poloxamers used include:

(1) Poloxamer 407
(2) Poloxamer 188

c. Amphoterics

Betaines

Betaine surfactants are very widely used in all sorts of cleansing formulations. Betaines are mild and foam well, contributing to viscosity of most formulations. Technically betaine surfactants are cationic surfactants, not amphoteric because they never are in an anionic state, but their performance is similar to other amphoterics so are generally classified as such. Betaine surfactants are formed from the alkylation of a tertiary amine with chloroacetic acid.

Typical betaines used include:

(1) Cocamidopropyl betaine

Amphoacetates

Amphoacetate amphoteric surfactants are found in mild shampoos and skin cleansers due to their irritation reduction properties, moderately good foaming in hard and soft water, and light conditioning effect. These products are produced through carboxymethylation of a fatty imidazoline and generally contain high levels of salt.

Typical amphoacetates used include:

(1) Sodium cocoamphoacetate
(2) Disodium cocoamphodiacetate

Propionates

Propionate amphoteric surfactants are used in many cleansing products because of their irritation reduction, moderate foaming, and light conditioning properties. Versions of propionates are considered salt-free, which can have advantages in certain formulations.

Typical propionates used include:

(1) Sodium cocoamphopropionate
(2) Disodium cocoamphodipropionate

d. Cationics

Quaternary ammonium compounds

Quaternary ammonium compounds are the primary conditioning agents found in rinse-off hair conditioners. Their positive charge adheres to the negatively charged hair. Quaternary ammonium compounds are synthesized by reacting a tertiary amine with an alkylating agent such as methyl chloride.

Typical quaternary ammonium compounds used include:

(1) Cetrimonium chloride
(2) Distearyldimonium chrloride
(3) Behentrimonium methosulfate

Alkyl amines

Alkyl amines are heavily used in hair-conditioning formulations. These materials are not true cationics as such, but are generally protonated in formulations with acids giving them cationic character below pH 7.

Typical amidopropyl amines used include:

(1) Stearamidopropyl dimethylamine
(2) Cocamidopropyl dimethylamine

Amine oxides

Amine oxides are used as foam stabilizers, viscosity boosters, and solubilizers in cleansing systems. At times these surfactants are listed as nonionic or amphoteric. Amine oxides are synthesized by oxidation of tertiary amines.

Typical amine oxides used include:

(1) Cocamine oxide
(2) Cocamidopropylamine oxide
(3) Dihydroxyethyl cocamine oxide

INGREDIENTS FOR CREATING THE NEXT GREATEST LIPSTICK

Author

Nick Morante
Owner of Nick Morante Cosmetic Consultants

ABSTRACT

Lipstick is a color cosmetic product that most consumers take for granted probably because it is such a ”simple” product. Formulators and marketers do not take it for granted as it is a money maker. It is so small and compact. There are so many of them out there- in every perceivable color- and many consumers just pick a shade they like and purchase it without really looking to see what is actually in it. This chapter addresses key questions about this ubiquitous cosmetic product category. These include, for example: what makes one lipstick better than another? What really goes into making a lipstick? and what ingredients can go into a lipstick formula to make it the next greatest consumer product? It also covers exactly what a lipstick is, and how formulators can improve on what is already on the market and how to keep up and generate new product distinctions in a context of a rapidly changing product.

4.1.2.1 INTRODUCTION

It may be small and simple but lipstick is one of the most important market segments in the color cosmetics market segment and even the entire cosmetics industry. It is probably the most varied cosmetic product in terms of SKUs. Of the over 50 brands of lipsticks currently on the market, there are almost 2000 different shade names. That's not counting some of the smaller unknown brands that just have local distribution. And most of these are just in the United States cosmetics market alone. Lipstick sales were *up* by almost 15% in 2011. This is significant growth and creates a huge amount of revenue for cosmetic marketers as well as increased market share for some brands. In a sluggish economy, the increase in lipstick sales helps companies improve their bottom line when they don't do well with expensive treatment products or high-end fragrances. As a cosmetic, some lipstick brands are even being targeted towards the men's market. But what makes lipstick such a unique staple in our industry?

A lipstick is a crystalline solid that is molded into a cylindrical shape and inserted into a swivel up cartridge for ease of application and storage. Various waxes and oils are melted and mixed together to create the sturdy and solid stick matrix. The various physical attributes that come from each type of lipstick are a result of the different fats and oils used in the formula. These physical attributes are responsible for the product's application, texture, slip, tackiness, shine, and length of wear. And these all can be changed by varying the ratios of the waxes, fats, and oils in the lipstick formula. But the ideal lipstick must have a very strong and sturdy crystalline structure.

When a formulator has come up with a suitable formula, the lipstick can be molded using a number of methods. They can be molded using metal book molds that may require flaming to eliminate seams from the molding process and any other surface flaws, giving the stick a smooth, even, and shiny surface free of defects. Another filling method involves the use of silicone molds, where the molten lipstick is poured into silicone inserts. These inserts allow for the filling of unusual shapes that were nearly impossible with conventional book molds such as sharp edges and sharp points. They can even have corporate logos embedded into the stick surface. The silicone molding process does not require flaming, as the sticks come out smooth with a shiny stick surface. However, the use of silicone-based ingredients must be used with caution in the silicone molding process because the silicones used in the formula may be too compatible with the filling process and cause problems. These different methods are standard for the filling of lipsticks in the cosmetics industry.

What sets one brand apart from another? What is the difference between a lipstick that wears for four hours and one that wears for eight to ten hours? These attributes have been sought after by lipstick formulators ever since the very first

lipstick was molded. And it has always been a challenge. In other words, it's not that easy. But lipstick formulas are relatively simple. So how exactly is it done? What ingredients go into making the next greatest lipstick?

Historically, a freestanding conventional lipstick is a combination of hard waxes, various lipids, and colorants. This combination allows for hardness, some flexibility on application, and adequate color payout. Waxes are the key component of any lipstick. The typical waxes used in a lipstick formula are Candelilla Wax (Euphorbia Cerifera), Carnauba Wax (Copernicia Cerifera), White Beeswax (Cera Alba), and some mineral-based waxes. You may also see other hard waxes used in a lipstick such as Japan Wax, Montan Wax, various amorphous Microcrystalline Waxes, Ceresin, high-melting-point Polyethylenes, and some others. Some even act as plasticizers to provide flexibility to the stick. Both Beeswax and Japan Wax are also available in synthetic grades. These are significantly cheaper to use than their natural counterparts but offer the same physical characteristics. These are the backbone of most lipsticks and are the main contributing factor to a strong crystalline structure. And there are different grades within each type of wax. These in combination with various lipids, fatty materials, and oils (polar solvents, vegetable-derived oils, and various esters) are the basis for most of the lipsticks that can be found at the cosmetics counter today.

Figure 1 Lipstick Ingredient Bases

When looking at the ingredient label for any of the lipsticks on the market, one will see that they contain many of the same ingredients. Those at the top of the ingredient list are the higher-concentration ingredients, and many at the bottom are incidentals. Somewhere at the top of this list you will see many of the same waxes

being used as well as oils and esters. The hierarchy remains quite similar. This doesn't make for much of a difference from formula to formula or brand to brand. Some may be slightly softer than others while others may have more color laydown. Some may exhibit more shine while others may seem to be tackier. All in all these are the characteristics that can be found in a conventional lipstick. However, when looking at the ingredients used, they are all relatively the same from formula to formula. Figure 1 shows examples of some common lipstick ingredients. These basic ingredients are all that is needed to create a lipstick. They may exhibit different characteristics; however, they are just all variations on the same theme.

All the textural differences mentioned above come from the variety of vegetable oils, mainly castor oil (*Ricinus communis* seed oil), esters, and other solvents that are available to the cosmetic formulator. There are many different vegetable oils, all with different feel characteristics. There are many different polar oils that can be used as a starting point in a lipstick aside from castor oil. Depending on the feel characteristics that are sought after, castor oil can be completely eliminated from the formula. Castor oil is used because it is an inexpensive polar solvent, it is convenient, and it works as a good pigment-wetting agent. But nowhere does it state that castor oil *must* be used to make a lipstick. Although it is the main solvent used to grind the pigments, other oils can be used.

4.1.2.2 WHAT ATTRIBUTES ARE WE LOOKING FOR IN A LIPSTICK?

First, what attributes are we looking for in a lipstick? Second, what new ingredients are out there and which of them will be suitable in a lipstick formula? And third, what ingredients will deliver these desired attributes? The main attributes that a consumer looks for in a lipstick are that it must be applied with comfort and maintain this comfort as long as it is on the lips, it must have and maintain a high degree of shine, and it must wear for a long time—no less than four to six hours. While these attributes may sound quite easy to achieve, in reality they are very contradictory. It is very easy to create a lipstick with high shine and nice comfortable feel, but to make it long wearing at the same time becomes the biggest challenge.

Shine is a function of melt, and melting means the product is wearing off because it is *liquefying*. Increasing the wear involves the use of polymers and film formers, and these are usually stiff and uncomfortable on the lips. Increasing wear can also involve increasing the powder loading, which may tend to dry out the lipstick, again affecting the comfort level of lipstick wearing. Conventional lipsticks cannot be made to contain all these attributes together in one product, what everyone in the industry calls "The Holy Grail of Lipsticks." Many formulators have used this phrase and it turns out to be quite true. It is sort of a balancing act, getting the most out of the ingredients to achieve the maximum level of positive attributes.

You can never perfectly achieve everything. I say positive, because along with positive you have negative. The negatives are what formulators try to combat in the product, such as tack, drag, and dullness. That's the tradeoff you get trying to achieve all the positives. So what new technology can be used to achieve all the positive attributes we are looking for in a lipstick? We will work up to that as we move forward in this chapter.

4.1.2.3 TRADITIONAL INGREDIENTS USED IN CREATING A LIPSTICK

The most common ingredients found in lipsticks are esters. There are thousands of esters that can be used in a lipstick formula. These range from light penetrating esters to heavy viscous liquids and pastes. The only limits to the number of esters that can be used are the different acids and alcohols that are used to create them. With so many different variations, the different feel characteristics that can be exhibited in a lipstick formula should be virtually limitless. And more esters are being developed, as the industry always requires them.

But by using the same ingredients over and over again all we are doing is creating an overabundance of "me too" type products on the market, differing only in the combination of ingredients used and not so much in new technology. This new technology can involve new types of ingredients, the science used to create them, as well as methods for manufacturing; but it is science that will play a key role in the next generation of lipsticks. It is this new technology that we will focus on in this chapter in order to create the next greatest lipstick. It is always technology that creates the point of difference in new products. Otherwise we will just wind up with another product in the "me too" category. It is quite easy, but certainly not considered groundbreaking.

Technology—what is it and how does it relate to lipsticks? After all, the cost of ingredients to make a simple lipstick is just a 5–10¢ combination of waxes, oils, and some other simple components. What can technology possibly do here? Since technology can involve a whole lot of different things, the bottom line is to do something entirely different. And the obvious place to start is with the ingredients. You don't need many ingredients in a formula to make it feel elegant. It is just the right choice of ingredients that will do the trick.

Of the different types of esters that can be used there is one group called Sugar Esters of Fatty Acids. These are a little different than conventional esters in that they are based mainly on the disaccharide Sucrose (common table sugar which is only derived from plant sources) as a starting point and reacted with a fatty acid to form the ester. Common sucrose fatty acid esters used in cosmetics are sucrose distearate, sucrose palmitate as well as a number of others. They can also be made from fatty acids derived from specific plants: sucrose cocoate, sucrose

polycottonseedate, sucrose polypalmitate, sucrose pentaerucate, or sucrose polysoyate, but any fatty acid can be utilized in the esterification process. There are a number of others, but they all cannot be listed here. Their functionality is dependent on the specific fatty-acid chain utilized. They contribute to feel and moisturization owing to their sucrose carbohydrate backbone. They are considered natural ingredients and are approved as direct food additives and even considered natural emulsifiers in some markets. The sugar aids in reducing water loss and helps with adhesion to the lips. Speaking of sugars and carbohydrates, sweeteners (both natural and artificial) are seeing more use in lip products along with different types of fragrances, flavorings, and maskants, and most are GRAS (Generally Recognized as Safe). You see these ingredients mainly in food products, as they are edible.

And speaking of fatty acids, a lipstick formulator can use some natural oils that are high in essential fatty acids. Depending on the oil selected, these provide various amounts of omega-3, -6, and -9 fatty acids. Some plant-derived oils, mainly from the seeds and nuts of the plants, are high in both omega-6 (linoleic acid) and omega-3 (linolenic acid) fatty acids. These are considered unsaturated fatty acids. So a formulator does not have to use fish oils to get the benefit of all three essential fatty acids. Not only do they possess excellent aesthetic properties, they can also be used to make skin care claims with restorative properties as well. For example, kukui nut oil is high in omega-3 and omega-6 fatty acids, so it should see benefits in cosmetics. Oleic Acid, a major component in olive oil, is an omega-9 fatty acid. There are also omega-7 fatty acids. These are also considered unsaturated and the site of unsaturation is seven carbon atoms from the end of the carbon chain. Rich sources of omega-7 fatty acids include macadamia nut oil and sea buckthorn oil.

The next step when using conventional esters of fatty acids is to look for molecules that have longer chains with unique substitutions and branching such as behenates, arachidonates, and erucates. These can add some unique properties to a lipstick formula such as creaminess, cushion, and body. They can be based on saturated or unsaturated fatty acids. This just creates more of a variety of esters based on the fatty-acid starting point. These higher-molecular-weight ingredients perform unlike any of the esters we are currently familiar with and can offer new and unusual feel properties to the lipstick. High-viscosity alky esters such as bis-diglyceryl polyacyladipate-2 offer creaminess and skin protection due to their film forming capabilities. Various butters (hydrogenated vegetable oils) can also serve this purpose.

Figure 2 is a chart that shows what ingredient ratios can be used to create different types of lipsticks. As we stated earlier, a lipstick is a combination of waxes and oils in sufficient ratios to produce a freestanding structurally sound stick. The final selection of waxes will be dependent on their individual melting points, hardness values, and sometimes solubility with the other ingredients in the formula.

While the choice of individual waxes may be the same (according to their INCI names), it is the grades of these waxes that may vary. As they are extracted from the plant, waxes have various fractions that have different hardness values and melt points. Different grades of the same wax may even differ in color and odor. This chart shows how the same ingredients can be used to create different types of lip products; most of them are sticks. Essentially there is very little difference in the ingredient selection to create these lipsticks. What if the choice of waxes were to change? What other waxes are available to the formulator that can be used to create a lipstick?

	LIP GLOSS PLOT	CREAMY LIP STICK HIGH SHINE	LONG WEAR LIP STICK	TRANSFER PROOF LIP STICK	LIP LINER STICK
WAXES	5–10%	10–15%	15–20%	10–15%	15–25%
VOLA TILES	NONE	NONE	15–20%	35–40%	VARIES
OILS AND SEMI-SOLIDS	70–80%	60–70%	35–45%	10–25%	40–50%
PIGMENTS/ POWDERS	5–10%	10–15%	10–15%	10–20%	15–25%

Figure 2

There are some new waxes that have been presented by wax manufacturers to the formulating community. These are neem wax, esparto wax, bayberry wax, sunflower wax, various polyester waxes (based on castor oil), jojoba wax, rice bran wax, and other naturally derived plant waxes that can create a suitable crystalline structure. These in combination with other conventional waxes can add a point of difference to a lipstick. There are silicone waxes that can be used in conjunction with the conventional waxes, which will add significant feel attributes as well as providing hardness to the stick itself. We still need the carnauba and candelilla for strength and shine and we still need to have beeswax for stick shrinkage and mold release. There are yet other waxes based on different chemistries that can be used to create a luxurious lipstick formula.

Hard waxes have a fairly narrow melting point range (around 3–5°C) and usually show a sharp transition when going from the solid phase to liquid phase. Soft waxes on the other hand have a much wider melting point range (around 10–12°C). These undergo a relatively gradual viscosity change around the melting point. This will be evident when running a drop point on the lipstick. The drop point is a relative measure of a product's melt viscosity but is

not exactly the same as its melt point. While the melt point may be sharp and happens quickly, the drop point will take longer for the product to move (drop) or *flow*. Rheology plays an important role in lipstick formulation. Rheology is very important in a lipstick, as one still wants to inhibit product *flow* especially at elevated temperatures. Even though a stick is a solid at room temperature and doesn't really flow, this will help maintain stick integrity when the temperature does start to rise. The stick may get soft as the temperature goes up but we don't want it to actually melt in its case. We will talk a little more about rheology later on in this chapter.

Silicone waxes act in very much the same way as typical hydrocarbon waxes (various grades of ozokerite or paraffin) in that they go through a phase transition from the solid phase to a fairly viscous liquid phase over a well-defined and predictable temperature range and can be controlled as the silicone molecule is synthesized. This phase transition usually occurs at or slightly above room temperature. What this means is that when a lipstick is applied, the user gets the benefit of a luxurious creamy laydown. Most silicone waxes are compatible with paraffin waxes, making them work well with many of the hydrocarbons we formulate with. Silicone waxes are unique because they have a much higher molecular weight than paraffin waxes and usually have a higher viscosity when they are liquids. Again, depending on the chain length, this can be controlled.

Silicone chemistry is becoming a very large and integral part of cosmetic formulations, and not only in lipsticks. They offer a wide variety of characteristics that are just not available from conventional ingredients. The worst part of using silicones is trying to pronounce some of the names and making sure they are spelled correctly on the ingredient label. Different silicone manufacturers are experimenting with their own silicone technology, knowing what the industry and cosmetic formulators are looking for. The addition of different oil-soluble groups to the silicone backbone results in materials that are highly desirable in cosmetic formulations. This creates a whole new class of ingredients with a huge variety of sought-after properties. Unlike plain dimethicone, alkyl dimethicone compounds are soluble in many oils, including mineral oils and petrolatums, esters and other oil-soluble materials due to the presence of the alkyl group. Alkyl silicones are extremely hydrophobic and are even insoluble in dimethicone. They are unique in that as the alkyl group increases, the hardness and melt point increase. For example, the alkyl chains of C32 and higher can have a melt point as high as 60°C or more. Conversely, as the silicone portion of the molecule increases, the softer the material becomes.

Silicone elastomers and blends are available as gels made with elastomer particles dispersed in a silicone-based carrier fluid or as a dry powder that can

be dispersed in a suitable solvent by the formulator into the product. These elastomer blends can vary greatly from high viscosity to low viscosity, from high tack to very low tack—all the properties that a formulator may look for in a lipstick ingredient.

Ingredients such as silicone polyglucosides. polymethylsilsesquioxanes, silicone polyvinyl acetates, stearoxymethicone/dimethicone copolymers, acrylate copolymers/hydroxypropylmethicone and polysilicone-11[1] along with many other different silicone compounds will add the positive feel and performance characteristics that lipstick formulators are looking for in a product. Some of these are silicone elastomers, which were first used in the medical field, are excellent film formers and easy to work with. If they were acceptable in that field, they certainly were safe and permitted for use in cosmetics, as safety testing would have been conducted on these materials as well.

Along with the waxes, there are the other main ingredients that go into making a lipstick. Here too, silicones can play a significant role in the outcome of the lipstick formula. Modifications in the silicone molecules can yield new ingredients with unique and novel feels and application characteristics. The remarkable thing about these silicone polymers is that modifying the chain with known positive properties, they can be made to feel comfortable on the lips, unlike the films derived from conventional polymers. Some prime examples are alkyl modified silicone compounds, silicone waxes, and other silicone derivatives currently being synthesized and investigated by today's silicone chemists. Depending on their molecular weight and chain length, these can be hard waxes or soft gels that offer a very wide variety of performance characteristics. Their compatibility and solubility with other ingredients is surprisingly quite good due to their chemistry.

Phenyl modified silicones such as trimethylsiloxyphenyl dimethicone have higher a refractive index than conventional dimethicones. That means they offer more shine than a regular dimethicone fluid. Since most silicone compounds are not noted for providing high shine, these can help alleviate that problem to some degree. They are clear and colorless like dimethicone and are available in various viscosities from 20 to 1000 cps. These are also very compatible with many different esters, some longer-chain alcohols, and other silicone compounds but not so much with hydrocarbons (which do not offer that much shine). They also can reduce the tackiness that is associated with acrylic acid polymers, which can be used to extend wear.

Different silicone manufacturers have different approaches to new silicone technology. So the lipstick formulator should "shop around" to see what is being developed by the various manufacturers and determine if there is a place for any of this new technology in a new lipstick formulation.

Conventional waxes have even been modified with silicones. There is siliconyl beeswax, siliconyl carnauba wax, siliconyl candelilla wax, and siliconyl polyethylene and even synthetic waxes[2]. The advantage of using siliconyl waxes is that it improves the compatibility and solubility of other silicones in a formula that would normally be very difficult to combine and work with. As science progresses, there may be other waxes based on silicones that will be made available to formulators. As the need for additional and different waxes increases, the development and introduction of these waxes will also increase.

There may also be synthetic waxes that can be based on chemical reactions. These waxes may be the by-product of the chemical reaction. One must be careful, as any chemical process has costs associated with it and if the process is refined or modified to cut costs, then the by-products may be reduced or even eliminated as a result. This means that the synthetic wax you have been using may have limited or no availability down the road. This also means that reformulation will be necessary no matter how fabulous the ingredient was. Most manufacturers will know this ahead of time and give sufficient lead time for the reformulation. Needless to say, the reformulation may not be that easy because the wax may have been that unique. That's probably why the wax was used in the first place.

No matter what the choice of waxes, it should be remembered that a suitable and stable crystalline structure should maintain a melt point no higher than 75°C and no less than 65°C. Stability at elevated temperatures is very important as lipsticks are sold in every market around the world and temperature conditions vary greatly throughout the year. The same formula can be sold in locations on the equator in the summer as well as northern Canada in the winter. So the same "global" formula must pass under *all* product stability conditions.

The next major hurdle to overcome is selecting the remaining ingredients that will contribute to all the positive attributes in the lipstick. Lipids, fats, oils, esters, soft waxy materials, etc. will all be needed to achieve the desired qualities one is looking for in the lipstick. But using all the same ingredients will only bring you back to that "me too" scenario. So we go back to new technology to achieve all of the desired attributes we are looking for. What is very important is to maintain stability and compatibility in the lipstick formula. The correct balance of polar and nonpolar solvents must be used in order to maintain stick structure and integrity, but polarity and pigment wetting are equally as important. Figure 3 shows how various emollients are categorized and classified in the world of cosmetic ingredients. This can be used as a gauge for compatibility of different ingredients in the same or similar formulas.

Figure 3

Most ingredients used in a lipstick are on the polar side but this polarity can vary from ingredient to ingredient. Nonpolar ingredients must be kept to a minimum in the formula as there are compatibility issues to be concerned with, which can sometimes lead to other problems such as *sweating* in the lipstick. This is something every formulator wants to avoid. Sweating can happen as the temperature of the lipstick rises and causes molecular movement. The liquid droplets usually reabsorb (leaving no marks on the stick surface) when the temperature equilibrates or comes back to room temperature. The worst situation is when a lipstick sweats at room temperature with no rise in temperature. This may be a sign of ingredient incompatibility and definitely will be very unappealing to the consumer. Sweating can also be treated and avoided by adding clays to the formula in the form of master gels.

Bentonite and hectorite clays pre-dispersed in a solvent can be added as a gel to the lipstick formula. The addition of these clays (in the form of gels) helps reduce and slow down molecular movement at elevated temperatures and can reduce or eliminate the incidence of sweating in the lipstick. As previously mentioned, rheology is a very important parameter in a lipstick. These clays tend to alter the rheology of the lipstick system and reduce flow characteristics. Within the lipstick's crystalline matrix the clays and other powders fill in the gaps between waxes and oils and prevent the liquids from seeping through when the temperature elevates. They are mainly used in cosmetic products for rheology and viscosity control. Since these clay master gels can be difficult to prepare in the lab (ionic placement is critical for proper viscosity build), it is much better to use them pre-made in the

form of the gels. There are many solvents that these gels are already prepared in, so the formula has a wide variety to select from.

Probably the most important attribute that is sought after by consumers as well as formulators is wear and longevity. Let's talk about this first, since it may be the most difficult attribute to deal with. While it may be easier to make a lipstick shiny and feel nice on the lips, making it wear long is not as simple as one would think. The ideal lipstick should last on the lips for at least six hours. The average lipstick has about four hours of wear, or less. This is extremely subjective because each wearer has different wear habits and may need to apply the lipstick regularly. Many people drink a lot, eat a lot, talk a lot, and just move their mouths, causing the lipstick to wear off sooner. Some people just enjoy applying lipstick. The object is to reduce this product movement or "transfer" by creating a film that does not wear off that fast. To get more than six hours is quite the challenge. But that is what marketers and formulators are striving for.

Feel and shine are the next most important lipstick characteristics. There are many ingredients available to the formulator to give a stick a very nice creamy feel and application as well as provide an abundance of shine on the lips. Some esters have a very high refractive index and provide a great deal of shine. Aside from polybutene-type ingredients, there are many new ingredients being introduced to the cosmetics industry, many from unusual sources, which can provide high shine.

While polybutenes and their derivatives provide extremely high shine, they can be extremely tacky on the lips and are synthetic in origin. Hydrogenated polyisobutenes maintain their shine but are much less tacky. Both the polybutenes and hydrogenated polyisobutenes come in various grades that have increasing viscosities. Some pour freely and some are almost solids and do not flow easily at all. These must be solubilized in compatible materials in order to make them usable in the formula.

4.1.2.4 TRENDY AND EXOTIC INGREDIENTS FOR LIPSTICK

A whole new group of ingredients is being made available to the cosmetics industry. These are being sourced from various rainforests throughout the world. They can come from the Amazon Basin in Brazil or as far away as equatorial Africa and Asia (see Figure 4). These ingredients, while offering unique feel attributes, are also quite functional. "All natural" is one of the directions the cosmetics industry is heading towards. Indigenous peoples and ancient civilizations used these as staple ingredients in their normal lifestyles because they worked so well in a variety of ways. This functionality is being transitioned into today's cosmetics and personal care products. What people routinely used these ingredients for in their everyday lives, cosmetic formulators are routinely making claims for in their products.

Figure 4

Ingredients such as copaiba balsam, andiroba oil, sange de drago (dragon's blood resin), açai butter, buriti oil, maracuia oil, and a host of others with strange-sounding names are becoming a very strong trend in many cosmetic products, including color cosmetics and lipsticks. These ingredients will add moisturization and emolliency to the lipstick as well as making the stick feel nice and creamy and at the same time providing shine. Included in this category would be various oily extracts derived from plant sources. While being a bit more costly than conventional ingredients, they can add some interesting claims to a product, which in many cases pays for itself in quality—especially for some of the major prestige and high-end brands.

Many peoples around the world used (and still use) the forest and what it offers as a source of all their daily needs (and livelihood): for food and nourishment, health and healing, cleansing and beauty, for barter and trade. Many of the characteristics we try to include in today's cosmetic products are based on what these ingredients have to offer. That is why there is such a concern over the decrease in the world's rainforests. As the rainforests disappear, so do the sources of these ingredients. Some of these ingredients can only survive in these specific environments and is sometimes their *only* source.

So we have all these new oil-soluble ingredients: solids, liquids, pastes. These can be added to a formula to create a great lipstick. But a formulator must know what ingredients to use in order to achieve a specific attribute, especially esters, which can and do vary greatly. Adding the wrong ester may not improve shine or increase creaminess on the lips. There are ways that this can be measured so that the correct ingredient is selected.

Figure 5

Spreadability is an important gauge in determining if an ingredient will be smooth when applied to the lips. So spreadability is important in determining how a lipstick will apply and how it will feel. It can be measured by comparing the different "spreading coefficients" that each ingredient possesses. With many ingredients, spreadability increases with polarity, increased molecular weight, and the degree of branching on the molecular chain. Figure 5 examines some common cosmetic ingredients and the difference in spreadability they provide. The lower the number, the "dryer" the ingredient will feel and the less it will spread. While spreading coefficient calculations and equations involve the spreading of an oil onto the surface of another liquid (usually water), relative to one another the liquids cited can still be compared against one another. After all, there is some thin layer of moisture on the lips when a lipstick is applied. For example, for a lotion with mineral oil used as a base, in order to spread freely and evenly on the skin (which contains some moisture if not really *dry* skin), its polarity and spreading coefficient can be increased with the addition of surfactants or emulsifiers in order to help it blend into the skin.

4.1.2.5 MISCELLANEOUS

Mineral oil and many other hydrocarbons and petroleum-derived ingredients can feel dry on application and have very little slip. So they may not offer as much creaminess or shine to a lipstick formula as a moderate molecular-weight ester

such as triisostearyl citrate (TISC) can. While they may be great for occlusivity and moisturization because of the films they generate on the lips, hydrocarbons add very little in terms of positive aesthetic qualities. While they are necessary in a stick formula to maintain good crystalline structure, stick formulations based on hydrocarbons and mineral waxes exclusively are put into an entirely different product category such as concealers and foundation sticks. Plus many formulators are staying away from mineral oil in many of their formulations. Light esters can feel dry as shown by their low spreading coefficients while different silicone oils begin to have higher slip by exhibiting spreading coefficients of 35 and higher. The use of volatile fluids should be avoided unless the formula actually calls for them. Here the package must be taken into consideration and must be airtight to prevent the loss of solvents. This may ultimately add additional cost to the product but it is something that cannot and should not be overlooked. There are times when special packaging may be required when a new product is developed.

The combination of ingredients with high-slip and oil-soluble film formers may also help increase wear. Such film formers that come to mind are the family of Ganex™ polymers (or their new name Antarons™). We have Ganex™ V220 (PVP/eicosene copolymer), a waxy solid, Ganex™ V216 (PVP/hexadecane copolymer), a liquid, and Ganex™ WP660 (PVP/triacontene copolymer), another waxy solid[3]. These were originally used mainly in hair care products for shine but can be used to create a shiny film on the lips. They are very compatible with many lipstick ingredients and high use levels are not that necessary to create an adequate film. What also can be investigated are anhydrous adhesives as long as they produce a flexible breathable film on the lips. Their adhesive properties should extend the wear of the lipstick. Once again, low levels should be used in order to avoid the product being too sticky on the lips.

The use of powder fillers can also add some unique feel properties to a lipstick. Nonabsorbent spherical silicas, boron nitride (BN), polymethyl methacrylate (PMMA), polytetrafluoroethylene (PTFE), and other specialty powders and polymers can provide a ball-bearing effect, greatly affecting the application characteristic of the lipstick. They provide a smooth slippery feel when applied and the lipstick tends to feel like it is gliding onto the lips. These ingredients come in various grades (opacity and particle size), so it is easy to make them "fit" into the formula, but the correct grade must be chosen in order for the lipstick to perform properly. A formulator can also use the various grades of synthetic nylon (nylon-6 and nylon-12) and natural silk powders (derived from silk protein) to enhance the feel and application properties. Many ceramic powders are used in cosmetics, especially for these unique feel characteristics.

Ceramic powders such as boron nitride require high heat and pressure in their manufacturing process. A reaction starts out with natural borax and a high-temperature

nitrogen source. Unlike spherical powder, these result in a lamellar structure where the powder particles glide over one another instead of roll. As these molecules do not exist in nature and must be synthesized, they cannot be considered natural materials even though their names imply that they may be mineral in origin. For a consumer, this can be very deceptive for a product's package and label copy. Since many ingredients are synthesized, some cosmetic feel characteristics can be as well.

Borosilicates are another class of effect pigments that due to their very smooth and flat particle surface and shape can also enhance the feel of a lipstick, whereas plain micas and other effect pigments have irregular shapes with jagged edges with different platelet thicknesses, and the larger particles can be felt on the lips. Calcium aluminum borosilicate and calcium sodium borosilicate are two such effect pigments in this category. They are a form of glass bead with a very controlled surface. There are other fillers that have a nice slippery feel, such as lauroyl lysine, an amino acid powder that is also used as a texture modifier. Yet there will still be other fillers that owing to their particle shape will enhance the feel of a lipstick. That's just the way our industry and new cosmetic ingredients have evolved. It is up to the formulator to come up with just the right combination of ingredients, such as the ones mentioned in this chapter, to get the optimum performance characteristics and the best positive properties out of the lipstick formula.

Particle size is very important, as it relates to feel. For instance, bronze and copper metallic powders have a very small particle size (and a large surface area) while glitter pearls, which are actually plastic polymers (polyethylene terephthalate or PET), can be very large. These glitters will most likely be felt on the lips. Glitter pearls are also hygroscopic and absorb moisture from their surroundings, including the lips. There are some particle-size restrictions for mica-type effect pigments (no higher than 150 microns) in some other cosmetic eye products. For non-mica pigments, good judgment should be used when using larger particles in any cosmetic product. Larger particles will impact the feel of the product. Pearls at 150 microns may feel raspy on the lips and for people with sensitive skin or lips, this is an absolute no no and should be avoided.

This brings us to the actual color additives, the ingredients that make a lipstick what it is—a product to deposit bright vivid color on the lips. But care must be taken here as well, as some colorants are highly absorbent and can feel somewhat dry or draggy on the lips. Colorants such as D&C Red Nos. 6 or 7 Lakes and Yellow Iron Oxide have a fairly high oil absorbance and will suck up a lot of liquid whereas colorants like FD&C Blue No. 1 Aluminum Lake and Titanium Dioxide do not suck up as much liquid as the colorants previously mentioned. This is evident as some dispersions will pour at a given color concentration and others will not at the same color concentration. The oil absorbance of all the powders in a lipstick formula can be calculated. There is a standard ASTM method for

this. These differences can be overcome by balancing the formula with a highly absorbent ingredient like alumina hydrate or an ingredient with low absorbance such as barium sulfate. In all cases colorants must be ground in a suitable solvent using a ball mill or three-roll mill. They can also be purchased from suppliers as pre-ground dispersions, so no grinding is necessary. This is ideal for cosmetic manufacturers that do not have grinding capabilities.

One of the more conventional ways of extending wear is to use staining pigments based on bromofluorescein dyes (such as Lakes of D&C Red Nos. 22, 28, and Orange No. 5) as colorants to the lipstick formula. These colorants, as with all other synthetic organic colorants, are used in the form of insoluble lakes. They start out as water-soluble dyes that are pH sensitive and will stain the lips bright pink well after the actual lipstick has worn off. These colorants are beautiful and create wonderful shades but they do have their drawbacks. Care must be taken when using them, as they are hygroscopic and absorb moisture from the lips. Using these pigments at too high a concentration may tend to dry out the lips, which again brings us back to the comfort factor.

Lipstick Pigment Levels

Light Coverage	4 - 6%
Medium Coverage	6 - 12%
High Coverage	12 - 18%
Super HIgh Coverage	18% (or higher)

Figure 6

Figure 6 shows the approximate use levels of colored pigments that can contribute to the various coverage levels in different types of lipstick formulations. The total level of color in the final product should always be considered, as the increase in color concentration usually has to be taken from other ingredients somewhere else in the formula, usually the oils, making the formula potentially dryer feeling. This doesn't take into account the pearls, which will also affect the lipstick feel when used at high levels. Pearls must be used in order to achieve a desired shade or specific effect.

The total amount of color additives, pearls, and other fillers used in the formula should be looked at very closely, as this will ultimately affect the final feel of the lipstick. While higher payoff may be a desirable attribute, this can also be accomplished by making the lipstick formula a little softer, which will also make it a little creamier and this should improve feel and shine at the same time. But excessively high pigment loading may also interfere with the lipstick's crystalline

structure and make it softer or even mushy. You go from crystalline to amorphous. While this may be acceptable for fingertip or brush application, it is highly unacceptable for a freestanding stick. It will just break too quickly, usually at its weakest point, the cup line, if too much stress is applied during application.

One way to check if a lipstick has sufficient crystallinity and hardness without the use of sophisticated equipment such as a Chatillon is to crush it between the thumb and index finger. While this is very qualitative, it does give a person a very good idea of exactly how a lipstick is supposed to feel when it breaks. When applying force, the lipstick should have resistance when squeezed harder and harder until it finally breaks. It should *snap* when it breaks, and this is a unique feel between the fingers. It should not crush and feel soft and mushy. This snap is something that is easily recognizable compared to a simple flat crush. A simple flat crush means the stick would be too soft with not enough crystallinity. The crystallinity is for lipstick strength and compatibility with a host of functional ingredients. It should also be strong enough (but obviously not too hard) for when it gets into the hands of the consumer, who will subject it to a myriad of stresses and strains.

The use of unconventional ingredients can result in a lipstick that has the desired qualities and still maintains a strong crystalline structure, making for a very stable stick. While there still may be a balancing act to overcome, achieving these goals by using ingredients that are not normally used should make it easier to balance feel, shine, and wearability without greatly sacrificing any of them. While there still may be a need for the use of conventional ingredients and polar solvents such as castor oil, which is used to wet out and grind pigments, a bulk of the formula will be made up of new and unique ingredients—getting away from the "me too" products that are on the market.

Also, a lot of the information presented here in this chapter comes from years of hands-on experience. Many of the basic concepts regarding lipsticks are written in books such as this, but the rest come from actually making batches at the bench. This also allows the formulator to understand what a lipstick is supposed to feel like and what combinations of ingredients to use in order to get there. While this may sound trivial, a formulator must have an acceptable stick structure that can be modified as needed with a wide variety of ingredients. Once the formulator is satisfied with the structure of the lipstick, the aesthetic properties of shine, feel, and longevity can then be adjusted. All the cosmetic ingredients cited in this chapter are readily available from multiple suppliers and distributors in the cosmetic industry.

Partnering with cosmetic ingredient suppliers and distributors can sometimes help the formulator in obtaining new and unique ingredients that will contribute to ideal aesthetic properties. Suppliers are searching the globe for new and sometimes

provocative ingredients that will enhance the properties of today's cosmetic products, including lipsticks. On a global scale, lipsticks are the one cosmetic product that consumers *cannot* live without. They are highly prized and very personal. You will always find a woman carrying at least *one* lipstick (and a mirror of some sort) in her purse or carry bag at all times. They don't go anywhere without it. In fact, women get very upset when their favorite lipstick shade is discontinued or no longer available.

It is hoped that the lipstick market segment sales figures will surpass and go far beyond 2011's 15% growth mark. The more novel and useful the ingredients are, the better the chance of creating that next greatest lipstick. If the product works, people will buy it. Good formulating skills and some experience will make this process a bit easier. With a little creativity and the understanding of how ingredients work, the next greatest lipstick won't be that far off. And that lucky formulator who creates it will really have something to be very proud of. I say lucky, because it will require a lot of work and searching for those special ingredients. The effort that a cosmetic formulator puts into creating the next greatest lipstick will truly be worth it. But which market will this great lipstick come from? Only time will tell, but it shouldn't be that far away.

ABSTRACT

This chapter describes the chemical and physical properties of hyaluronic acid and its cleaved, lower-molecular-weight fragments as well as its derivatives relative to their interesting and useful topical application to moisturize skin in anti-aging products.

TABLE OF CONTENTS

4.1.3.1 Structure and selected physical-chemical properties of hyaluronan **606**
4.1.3.2 Preparation of hyaluronan fragments, isolation and characterization thereof, characterization of degradation products of hyaluronan **607**
4.1.3.3 Preparation of chemical derivatives of hyaluronan, characterization thereof **610**
4.1.3.4 Hyaluronan penetration into the stratum corneum and into the skin **612**
4.1.3.5 Moisturizing properties of native high-molecular hyaluronan and how the moisturizing properties change as the molecular weight is reduced **613**
4.1.3.6 Selected Derivatives of Hyaluronan and their Effect on Skin Moisturizing **616**
4.1.3.7 Cosmetic application for various molecular weights of hyaluronan **617**
References **618**
Glossary **621**

4.1.3.1 STRUCTURE AND SELECTED PHYSICAL-CHEMICAL PROPERTIES OF HYALURONAN

Hyaluronan (HA) is a naturally occurring linear polysaccharide consisting of alternating β-1,4-linked units of β-1,3-linked glucuronic acid and *N*-acetyl-D-glucosamine (Figure 1.1). HA is a main component of the extracellular matrix in connective, epithelial, and neural tissues and is known to play an important role in the tissue hydration and water transport mainly due to its enormously high water-binding capacity. The high water-binding capacity of HA can be attributed to high density of fixed negative charges in HA chains from carboxyl groups, which causes the osmotic pressure and draws the water molecules into the tissues containing HA.[1] For example, HA within skin layer holds up 1000 times its weight in water molecules.[2] Additional biological functions of HA include maintenance and viscoelasticity of liquid connective tissues such as joint synovial fluid and eye vitreous, supramolecular assembly of proteoglycans in extracellular matrix, and numerous receptor-mediated roles in cells, mitosis, migration, tumor development, and metastasis and inflammation.[1]

Figure 1.1 Hyaluronan (HA) structure.

The extensive repertoire of HA biological functions suggests the existence of different conformations and specific binding interactions.[3] It is likely that the conformation is affected by the local environment, including ionic strength and specific ion interactions, and the presence of interacting species including proteins and lipids. In the extracellular matrix, under normal physiological conditions and ionic strength, HA is generally believed to exist as a crowded random coil molecule.[4] A change in HA conformation is suspected under specific pathological conditions. Lowering the pH results in protonation of carboxyl groups and increased solution viscosity. In contrary, there is a polyanion contraction with rising ionic strength

due to the increased electrostatic shielding of HA. This latter effect is accompanied by a decreased solution viscosity. The HA solution viscosity is also temperature dependent and is a function of the overlapping parameter, molecular weight and concentration.

Some applications involving HA as an active ingredient require filtered HA solutions. The question that arises is whether filtration changes the physical-chemical properties of HA or not. According to our unpublished results, when proper dilution is used, filtration of HA (from 15 kDa up to 1.7 MDa) solutions through 0.22 μm nylon filter had no impact on molecular weight, polydispersity, and solution viscosity. The filtration impact on biological properties has not yet been established.

The major disadvantage of native HA is its low resistance against enzymatic degradation and short half-life after internal administration due to natural scission by enzymes and degradation by radicals. For this reason, at the present time the main challenge is the design of new HA materials that retain or increase the hydration properties of the polysaccharide and at the same time last longer in the application point. In order to increase the biological resistance of HA towards enzymatic degradation, modifications are being introduced in HA structure.[5,6] Another challenge is to synthesize HA derivatives with altered and specific physical-chemical and biological functions. Since the biological properties are connected with the HA molecular weight, there is also a great interest in HA degradation and evaluation of biological behavior of HA fragments.

4.1.3.2 PREPARATION OF HYALURONAN FRAGMENTS, ISOLATION AND CHARACTERIZATION THEREOF, CHARACTERIZATION OF DEGRADATION PRODUCTS

Disintegration of the HA β-linkages leads to formation of hyaluronan fragments of different sizes, identified by a name that indicates the number of monosaccharide units of which they are composed, e.g., a tetramer consists of four monosaccharide units—two glucuronic acids and two *N*-acetyl-D-glucosamines (GlcNAc). The name of the other fragments is created analogically. Fragments comprising more units are characterized by average molecular weight in Daltons. Thus, an eicosamer having 20 subunits is in literature specified as 20-mer, but it is also possible to say HA of molecular weight 4 kDa.

Mechanisms of the HA cleavage into its smaller fragments comprise enzymatic, free radical, thermal, ultrasonic, and chemical methods such as acid and alkaline hydrolysis.[7] Non-enzymatic reactions proceed randomly, and by this means mixtures of HA saccharides with different molecular weight can be obtained. By contrast, enzymatic cleavage is selective and allows preparation of HA

oligosaccharides with specific structure. Enzymatic digestion is catalyzed by two main types of enzymes—hyaluronate lyase and bovine testicular hyaluronidase (BTH).[8] Both enzymes produce fragments that contain an even number of saccharide units with GlcNAc at the reducing end. While HA oligosaccharides obtained by BTH are fully saturated, hyaluronate lyase produces oligosaccharides with the double bond between C-4 and C-5 position of uronic acid at their nonreducing end. Both saturated and unsaturated HA oligosaccharides lose under alkaline conditions GlcNAc from the reducing terminus with formation of odd-numbered oligosaccharides.[9]

During non-enzymatic cleavage, HA can be partially transformed into undesired degradation by-products exhibiting unwanted biological properties like carcinogenesis. Their identification is important so as to suggest ways of their elimination and to offer a final fragmented HA product free of toxic impurities. Until now only degradation by-products arising from acidic and alkaline hydrolysis have been established. Cleavage of hyaluronan under alkaline conditions gives a mixture of stereoisomers (*E*)-3-dehydroxy-3-en-D-GlcNAc and (*E*)-3-dehydroxy-3-en-D-ManNAc,[8] while acid hydrolysis of hyaluronan leads to creation of furan-like derivatives and derivatives of cyclopentanone.[10] These degradation by-products can be removed from the reaction mixture by ultrafiltration through a membrane of suitable cut-off.

Physical-chemical properties and biological activity of native HA significantly differ from its low-molecular-weight fragments. While high-molecular-weight HA is a space-occupying material and contributes to the structure of the extracellular matrix and tissue integrity, smaller-sized HA fragments are involved in a wide spectrum of complex biological mechanisms. From the cosmetic perspective, the most important properties of HA fragments involve stimulation of angiogenesis and supporting the proliferation of fibroblasts. Pro-angiogenic properties are exhibited especially by short HA oligosaccharides comprising from 6 to 20 saccharide units. HA oligosaccharides are mitogenic for endothelial cells, support their migration, and induce multiple signaling pathways.[11] Their good biocompatibility and low toxicity make them an ideal therapeutic agent for the situations when stimulation of new blood vessel growth is needed. *HA oligosaccharides are also components of dermatological compositions for combating hair loss and stimulating hair growth*. In the field of reproductive medicine, HA oligosaccharides may help fertilization.

Hyaluronan fragments can also be used for treating and preventing wrinkles, expression lines, fibroblastic depletion, and scars. HA oligosaccharides (with molecular weight <5 kDa) contribute to the suppression of wrinkles in both layers of the skin. At the epidermis, they stimulate the endogenous synthesis of high-molecular HA, which has a positive effect on hydration. At the level of the dermis,

HA fragments decrease the creation of pro-inflammatory interleukins, which are responsible for generation of free radicals capable of damaging both components of the extracellular matrix and the skin cells themselves. The most ambitious application of HA oligosaccharides is treatment of cancer. Anti-tumorigenic effects of HA oligosaccharides are based on their ability to sensitize cancer cells to treatment. The binding of oligomers to the HA receptors also inhibits the pro-tumorigenic signaling of high-molecular-size HA. Some low-molecular-weight HA molecules are believed to release strong immune reaction to the cancer cell.[12-14]

Analytical Techniques for Characterizing HA Molecular Weight

Since the length of HA polysaccharide chain is closely related to its biological functions, it is necessary to determine its molecular weight properly. A range of analytical techniques has been employed to assess the sizes of HA fragments. These were originally determined from the ratio of total glucuronic acid concentration to that of the reducing end GlcNAc group. More recently, other methods including viscosimetry, electrophoresis, mass spectrometry, and liquid chromatography have been used.[15] Electrospray ion mass spectrometry (ESI-MS) is mainly used for molecular weight characterization of short HA oligomers (up to 40-mer) derived from enzymatic digestions.[16] Enzymatic degradation provides a complex mixture of even-numbered HA oligomers, which must be fractionated using suitable techniques such as electrophoresis or liquid chromatography before ionization. ESI-MS utilizes a flowing stream containing the analyte and provides gentle ionization. Proper care must be taken in setting the cone voltage that accelerates the ions into the mass analyzer because high values of the cone voltage may result in an artifact of an increase of charged species. By contrast, low cone voltage leads to insufficient ions. At lower cone voltage it is possible to observe odd-numbered HA oligomers as artifacts in ionization.

As in the ESI-MS technique, it is not possible to avoid fragmentation of larger HA oligomers; it is advisable to use MALDI-TOF. This technique is suitable for characterization of polydisperse mixtures; it presents tolerance towards salts and buffers and is highly sensitive.[17] However, MALDI-TOF cannot be considered a quantitative method because desorption of HA fragments differs according to their size extensively. These complications can be overcome by using size-exclusion chromatography (SEC) coupled with multi-angle light scattering detector (MALS) and refractive index (RI), which provides detailed information of molecular weight, molecular weight distribution, molecular size, and solution properties in a wide range of HA fragments.[18] A limitation of the technique is that an SEC column cannot separate HA fragments sufficiently. Hence, two SEC analytical columns packed with an appropriate resin and connected in series are the possible solution for the separation of HA fragments. In this set, the length of the analysis is still acceptable.

4.1.3.3 PREPARATION OF CHEMICAL DERIVATIVES OF HYALURONAN AND THEIR CHARACTERIZATION

As it has been mentioned earlier, native HA suffers from its low resistance towards enzymatic digestion. This means that native HA has a high rate of *in vivo* turnover, which limits the period of time during which HA may act in the place of application. For this and other reasons, chemical modifications of HA intended for cosmetic or pharmaceutical applications are recommended. Chemically modified HA derivatives are also usually more mechanically robust and thus they are more suitable for final products manufactured using higher temperatures, pressures, or shear stress. *Modified HA derivatives usually have stronger binding capacity to the skin*, and as a result they are not washed off as easily as unmodified HA. An extensive research has been developed for chemical modification of HA. The strategies employed can be divided into two categories. The first one involves chemical attachment of pendant groups to change the properties of the polysaccharide and modulate the hydrophilic character of HA. The usual aim of these modifications is to lower the hydrophilicity of HA, so that the modified biopolymer will be able to blend with hydrophobic materials typically used in cosmetic products.

The second strategy for chemical modification of HA involves cross-linking in order to prepare insoluble derivatives of HA or hydrogels.[19] In fact, almost all of the commercially available HA products are stabilized by cross-linking to obtain materials with longer residence times and increased mechanical robustness.

Regardless of the modification strategy, the new, modified HA materials should remain biocompatible and biodegradable, as well as retaining the moisturizing properties. A critical point in the synthesis of HA derivatives is the preservation of the original chain length, since HA lubricant, shock-absorbent, and space-filling properties are closely correlated to its high viscosity, which is directly related to the initially high molecular weight of the biopolymer. From our personal experience, degradation is always inevitable during chemical modification processes.

Chemical modification of HA

Such modification can be carried out by the addition of the following functional groups to the polysaccharide backbone: carboxyl, primary or secondary hydroxyl groups, or the amino group after deacetylation. The chemical modification of carboxyl group is often preferred because it is the recognition site for HA natural receptors and hyaluronidase.[20] This method of modification may decrease the HA susceptibility towards enzymatic degradation.[21] However, the biological behavior of the polysaccharide, including its biodegradability, may change after such derivatization. Thus, the effect of each modification on the biocompatibility of the polysaccharide must be investigated in order to characterize the result on its properties.

HA coupling via its carboxyl group requires its previous activation to make it reactive to nucleophiles. The modification of carboxyl groups produces new amide or ester bonds in HA backbone. The typical reagents are the same as those used in common peptide synthesis, such as water-soluble carbodiimides (EDC and derivatives), carbonyldiimidazole (CDI), carbonyltriazole (CDT), N-hydroxysuccinimide (NHS), *p*-nitro-phenol, p-nitrophenyltrifluoracetate, and ethyl chloroformate (ECF). Chemical modification of HA is primarily performed in water or in organic solvent. To carry out modification in organic solvents such as DMSO, DMF, or formamide, a previous conversion of sodium hyaluronate to its acid form has to be done. However, this conversion drastically degrades the polysaccharide. Thus, the modification in water is always preferred. Previously enounced methodologies are in general patented and very well known by people skilled in the art. These strategies have been used for the synthesis of nano-emulsifiers,[22] films,[23] hydrophobized HA,[24] or hydrogels.[25]

On the other hand, the modification of the hydroxyl groups may involve the formation of ether bonds by reaction with bis-epoxides.[26] An example is the commercially available **Juvederm®**, a commonly used filler in cosmetic surgery. This product is chemically cross-linked by divinyl sulfone. Hydrophobized HA can be synthesized via formation of carbamoyl bonds after activation of hydroxyl groups.[27] The oxidation of the primary hydroxyl has been used for bioconjugation with lipids and subsequent hydrophobization.[28] However, some allergic reactions have been recently reported for commercially available products,[29] and so new challenges have appeared for scientists devoted to HA chemistry.

In the case of the formation of insoluble derivatives of HA (hydrogels), the capacity to retain water by the polysaccharide should be always determined by measuring the degree of swelling. *The denser the hydrogel is, the lower its water uptake capacity and swelling ratio.* In fact, regarding HA, most of the experimental data indicate that high swelling ratio values correspond to the lowest modification of the biopolymer. Low degree of substitution usually results in the formation of hydrogels with low cross-linking density, resulting in larger absorption of water and thus high swelling ratio. Conversely, high degree of substitution helps to form homogenous and more compact hydrogel network with lower water uptake capacity. Compression tests are often used to determine the smoothness of the hydrogel. Additionally, rheological studies are essential to evaluate the effect of derivatization or crosslinking.[30] Typically, the rheological behavior of HA and its derivatives is characterized by non-Newtonian behavior. The mechanical integrity of HA hydrogels is usually determined by measuring shear modulus (G), the larger the G value, the more resistant network towards deformation. The G value usually increases with increasing HA modification. After chemical modification it is always necessary to evaluate the effects of the derivatization on the physical, chemical,

and biological properties of the polysaccharide, as well as possible degradation during the process.[31]

4.1.3.4 HYALURONAN PENETRATION INTO THE STRATUM CORNEUM AND INTO THE SKIN

Skin is the largest reservoir of HA in our body, since it accounts for 50% of the total body HA content. Under ideal conditions, HA is found in all the layers of the epidermis and dermis. In the epidermis, HA is most prominent in the upper spinous and granular layers, where most of it is extracellular. By contrast, the basal layer of the skin also contains HA but it is predominantly intracellular. Presumably, basal keratinocyte HA is involved in cell-cycling events, whereas secreted HA in the upper outer layers of epidermis is part of the mechanism for dissociation and eventual sloughing of cells. The HA content in the dermis is far greater than that of the epidermis, and this accounts for most of the HA content in skin. The HA of the dermis is in equilibrium with the lymphatic and vascular system, while epidermal HA is not.[2]

Both epidermal and dermal cells are able to synthesize HA throughout our lifetime. However, *the skin cells lose their ability to produce optimal amounts of HA during the aging process. That is why the skin of babies is very rich in HA and is so soft, full, smooth, and supple, while with increasing age dehydration occurs; the skin thins and wrinkles appear.* The decline in HA production is also accompanied by a decreased suppleness, reduced elasticity, and loss of skin tone. The most dramatic histochemical change observed in senescent skin is the marked decrease in epidermal HA. In senile skin, HA is still present in dermis, whereas the HA of the epidermis has disappeared entirely. In fact, recent studies have indicated that the total level of HA in dermis remains constant with aging. However, at the same time, the proportion of total glycosaminoglycan synthesis devoted to HA is greater in the epidermis than in the dermis, and the reasons for precipitous fall with aging is unknown at the present time.

In order to retain the aesthetic appearance of the skin, and treat the signs of "dermatological" aging, it is recommended to keep "refilling" skin with HA from adolescent age onwards. It is already known that HA taken orally does not show any benefit to skin, because skin cells are not able to extract HA from the bloodstream.

The more reliable HA skin refill is by applying HA topically. Topical application of high-molecular-weight native HA (>500 kDa) is not recommended, because it does not efficiently penetrate the deeper skin layers mainly due to its large size. Instead it forms films that act as barriers against moisture loss.

Conversely, HA fragments sized smaller than 500 kDa are claimed to permeate and moisturize the skin. An efficient uptake of HA (357 kDa) by epidermis is indicated in Figure 4.1, where an isotopically labeled ^{14}C-HA was incubated with full thickness porcine ear skin using Franz diffusion cells at 37°C for 48 hours. *However, at the same time there was hardly any HA uptake deeper into dermis layers.* This *in vitro* penetration test into the porcine skin should resemble what will, with high probability, occur *in vivo* in humans. The results suggest that HA of 357 kDa applied topically is useful for the replenishment of HA levels in epidermis but is still too large to efficiently penetrate into dermis. Smaller HA fragments are then needed for more efficient penetration when dermis targeting is required.

Figure 4.1 Penetration of HA Fragments: ^{14}C-HA activities within 200 μm skin slices (pigs ear) after 48 hours penetration at 37°C.

4.1.3.5 MOISTURIZING PROPERTIES OF NATIVE HIGH-MOLECULAR-WEIGHT HYALURONAN AND HOW THE MOISTURIZING PROPERTIES OF HYALURONAN CHANGE AS THE MOLECULAR WEIGHT IS REDUCED

Due to the unique hydration, viscoelastic, and biocompatibility properties of HA and in view of a range of molecular-weight materials' ability to penetrate skin, *HA is being extensively used in cosmetic products as moisturizer, thickener, and stabilizer*. Since HA is a water-soluble product, it can be easily incorporated in the water phase of cosmetic formulas.

Due to its negative charge, HA is incompatible with cationic compounds or proteins at certain concentrations. A typical concentration of HA in cosmetic products varies between 0.01 and 0.2%[32]. *HA is suitable for application in a wide range of cosmetic compositions devoted to skin care and designed for topical applications.* Typical cosmetic products supplemented with HA molecules include serum,

moisturizers, creams, shampoos, conditioners, and bath oils. The benefits of HA being in the formulation are usually connected with reduction of the dermatological aging, reduction of the depth of lines and wrinkles (including fine lines), decrease of skin fragility, amelioration of skin atrophy, improvement of skin firmness and texture, decrease in pore size, restoration of skin brightening, and improvement of skin barrier function.

In hair-care and hair-treatment formulations, HA restructures the keratin fibers "inside" the fibers, improves elasticity of hair, and increases the washing resistance of colored hair.

The advantage of HA over other widely used moisturizers (glycerin, propylene glycol, and sorbital, polyethylene glycol) resides in the fact that its moisturizing properties are not significantly influenced by relative humidity. Unlike the other moisturizers, HA is able to keep good water retention capacity both at low and high relative humidity. In contrast, common moisturizers at low humidity and/or under xerotic conditions (dry skin, deep wrinkles, and squamous skin) absorb moisture from the inner skin rather than from the air, which in turn causes the skin to dry out. Together with other substances, HA belongs to Natural Moisturizing Factor (NMF) substances, which are hygroscopic, act as a surfactant, and buffer the skin thereby preserving its aesthetic appearance.

The moisturizing properties of HA are related to its hydration, often referred to as an average number of water molecules affected by the presence of HA anion in aqueous solutions. HA hydration was studied using several approaches including NMR,[33] viscosimetry, ultrasonic velocimetry, and thermal analyses.[34] Among these, thermal analyses, namely differential scanning calorimetry (DSC), is able to estimate i) non-freezable bound, ii) freezable bound, and iii) free water due to their different thermodynamic properties caused by the presence of HA (Figure 5.1). The non-freezable bound water is the fraction of total water content that is in close contact with HA surface and it is supposed to be either hydrogen bonded to HA molecules or is restricted by junction zones formed by HA chains. The freezable bound water is the next layer, which interacts weakly with HA molecules and non-freezable water layer. Free water is not influenced by HA and its properties resemble pure water. Therefore, it is mainly the amount of non-freezable and freezable bound water, which is considered as the number of water molecules hydrating HA structure. The number of bound non-freezable water molecules in 650 kDa HA is 7.6 per disaccharide HA unit. In terms of freezable bound water, the hydration increases up to 43 molecules per HA disaccharide unit.[35] In terms of grams, this means that 1g of 650 kDa HA can strongly hold from 0.8 to 2g of water. Further DSC results indicate that the water-binding capacity is independent of molecular weight from 30 kDa up to 750 kDa. Increased hydration (for about 0.12 g of water per g of HA) was detected for 1.4 MDa HA.[36]

Figure 5.1 Depiction of freezable-bound, non-freezable-bound and free water molecules in the presence of HA

To estimate the effect of different molecular-weight HA on skin hydration properties, a group of volunteers (n = 8) applied for 60 days (1 time per day) an o/w emulsion containing 0.005% native or fragmented HA. The hydration results reported in Figure 5.2 indicate that in the case of smaller HA fragments, namely 4.6 and 17 kDa HA, there is a significant skin hydration capacity increase after the first month of emulsion application. This result is in agreement with easier and faster penetration of smaller-sized molecules into the skin and with the fact that at epidermis small HA fragments stimulate the endogenous synthesis of high-molecular HA and in this way positively affect skin hydration properties. However, the more efficient hydration tendency of small-sized HA fragments was completely suppressed after another two months of emulsion application, where the best results were obtained for the native 1.66 MDa HA. As it was discussed above, the high-molecular-weight HA did not penetrate the skin but formed an efficient barrier against moisture loss. The results of the three-month study indicate that the skin hydration capacity is both HA molecular size and application time dependent.

Figure 5.2. Changes in hydration capacity of skin after the treatment with 0.005% HA in o/w emulsion.

4.1.3.6 SELECTED DERIVATIVES OF HYALURONAN AND THEIR EFFECT ON SKIN MOISTURIZING

Although a great number of HA derivatives have been synthesized in the last 15 years, there is a scarcity of literature devoted to the impact of HA modification on its moisturizing properties.

In general, it is believed that increasing the hydrophobic character of HA will enhance its penetration through the hydrophobic stratum corneum into the epidermis. Then, due to the fact that the permeability of substances through skin is not only related to their lipophilic character but is also inversely related to their size, small-sized hydrophobic HA fragments should theoretically favor transdermal transport.

To approve or disapprove the theoretical prediction, hydrophobized HA (50 kDa HA modified with 50% of hexyl functional groups) was tested *in vivo* for moisturizing effect. Similarly as in previous case, hydrophobized HA was integrated in o/w emulsion, which was daily applied by a group of eight volunteers. The changes in skin hydration capacity were compared to other two groups of volunteers using placebo and 17 kDa HA (Figure 6.1). In this case, the results indicated that the hydrophobized HA enhanced skin hydration capacity comparably to unmodified HA fragment. However, the effect on skin-moisturizing properties of tailor-made hydrophobic HA derivatives is unknown and still remains to be elucidated.

Figure 6.1. Changes in hydration capacity of skin after the treatment with 0.005% unmodified and hydrophobized HA in o/w emulsion.

Brown and colleagues[37] found that topical unmodified HA significantly enhanced the partitioning of both diclofenac and ibuprofen into human skin when compared to an aqueous control, pectin, and carboxymethylcellulose. This suggests that glycosaminoglycans, when allowed to interact with water, can enhance the percutaneous penetration of some drugs and cosmeceuticals useful in cosmetics and personal care. The details of their interaction remain to be elucidated.

In this matter, hydrophobized HA may represent even more efficient transdermal drug delivery systems because of two main reasons. First, as it was mentioned earlier, the partial hydrophobicity should increase the permeation rate of HA through the stratum corneum. Second, the hydrophobized HA contains both hydrophilic and hydrophobic functional groups, which under certain conditions may enable formation of micro and nano vehicles. These are able to increase the stability of poorly soluble lipophilic components and nutrients. The transformation of HA molecules into liposomes, microemulsions, or polymeric micelles can be used in transdermal research as a better alternative method to enhance permeation of components through skin. In fact, penetration of small hydrophobic drugs from such delivery systems into the epidermis can be increased more than two times.[38] Unlike other polymeric based delivery systems, HA-based polymeric micro and nano structures have major advantages due to excellent biocompatibility and biodegradability of the backbone. Thus, the feasibility of native HA and its derivatives for the development of new materials for applications in cosmetic, biomedical, and pharmaceutical fields is still under review.

4.1.3.7 COSMETIC APPLICATIONS FOR VARIOUS MOLECULAR WEIGHTS OF HYALURONAN

The skin hydration process proceeds through a very complex mechanism. Regarding HA, the whole range of molecular weights of HA is related to skin moisturizing. However, as it was described in details above, the exact moisturizing mechanism differs with HA molecular weight. For this reason, the choice of HA fragment for cosmetic composition should be always considered in context with intended reason of use and application. Simplifying the problem of Mw choice, the larger the Mw of hyaluronan the more predominant are physical-chemical properties, while biological properties will prevail in case of smaller Mw fragments.

For this reason, high-molecular-weight HA (about 1 MDa) is usually added in cosmetic formulation in order to increase composition viscosity and improve the stability of composition film when applied on skin. In this way, high-molecular-weight HA has positive effect on hydration of upper epidermis layers, which is manifested by lower trans-epidermal water loss (TEWL). Penetration properties (and thus anti-aging effect) of high-molecular-weight HA can be improved by combination of HA with skin penetration enhancers.

HA with molecular weights around 250 kDa enables deeper skin hydration due to its deeper penetration, where HA interacts with skin cells and extracellular matrix components. It is efficient in skin texture enhancement and wrinkles reduction.

Very small HA fragments (50 kDa and below) are very useful in anti-aging because after their penetration into deeper skin layers they serve as signal molecules for skin cells to synthetize new HA molecules. In addition, small HA fragments are

easily hydrophobized and in this way they penetrate deeper into epidermis and dermis, enhancing skin hydration capacity and enabling deep transdermal transport of complexed or bound hydrophobic actives from formulation.

GLOSSARY

Angiogenesis: The development of new blood vessels.

Anti-tumorigenic: Tending to suppress tumors.

BTH: Bovine testicular hyaluronidase, EC 3.2.1.35.

DMF: N,N-Dimethylformamide

DMSO: Dimethyl sulfoxide

Endothelial cell: A thin, flattened cell, a layer of them lines the inside surfaces of body cavities, blood vessels, and lymph vessels, making up the endothelium.

ESI-MS: Electrospray Ionization Mass Spectrometry. An analytical technique that can provide both qualitative (structure) and quantitative (molecular mass or concentration) information on analyte molecules after their conversion to ions.

GlcNAc: N-acetyl-D-glucosamine

HA: Hyaluronic acid, hyaluronan.

Inflammation: The end result of the different bodily processes, in response to an injurious agent.

Interleukins: A variety of naturally occurring polypeptides modulating inflammation and immunity.

MALDI-TOF: Matrix-Assisted Laser Desorption/Ionization –Time Of Flight. A method of mass spectrometry in which laser radiation of analyte-matrix mixture results in the vaporization of the matrix which carries the analyte with it. Ion´s mass to charge ratio is determined via a time measurement.

MALS: Multi-Angle Light Scattering. An analytical technique for determining absolute molar masses, sizes and conformation of all types of macromolecules.

Mitosis: The process where a single cell divides resulting in generally two identical cells, each containing the same number of chromosomes and genetic content as that of the original cell.

Mitogenic: Causing mitosis.

NMF: Natural Moisturizing Factor

Pro-angiogenic: Tending to promote angiogenesis.

Pro-inflammatory: Tending to promote inflammation.

Proliferation: The reproduction or multiplication of cells.

SEC: Size exclusion chromatography. A method in which molecules in solution are separated by their size**.**

AYURVEDA IN PERSONAL CARE

Author

Smitha Rao MS, MBA
Lonza
70 Tyler place South Plainfield NJ 07080

ABSTRACT:

Ayurveda is the ancient Indian system of medicine for well-being and longevity. Ayurveda, roughly translated as the "knowledge for long life" is one of the oldest forms of traditional medicine based on the Hindu principles. The practice of Ayurveda dates back to 1200 BCE, focusing on plant-derived ingredients for medicinal benefits. The philosophies of Ayurveda address the overall well-being of an individual and the principles are therefore aligned to cure the cause of an ailment and not the symptom. Ayurveda combines the wisdom of medicine and plant-based natural ingredients to provide a natural remedy for ailments, by a combination of oral and topical applications. The values of Ayurveda are ever more pertinent for personal care applications in industrialized countries. In particular, consumers from Europe and North America are trending towards sustainable and green personal care. Eastern philosophies of Ayurveda using natural, botanical extracts offer a holistic approach to personal care that is both green and sustainable. In recent years, a strong body of scientific evidence suggests that Ayurvedic treatments are just as effective in personal care applications for cosmetic benefits compared to traditional chemistries. Ayurvedic herbs have been used in skin care for a variety of benefits like brightening, sun-protection, anti-aging, anti-inflammatory, and antioxidant. Recipes created with Ayurvedic herbs can also be found in hair care application with scalp-health enhancement, prevention of hair-thinning, and hair fail benefits. This section focuses on the variety of commonly used Ayurvedic botanical extracts, their proof of concept, and their claims in personal care. This section will also address the critical factors that influence the future success of Ayurvedic ingredients for topical applications.

4.1.4.11 BACKGROUND AND FOLKLORIC USE OF AYURVEDIC MEDICINE

The origin of Ayurveda dates back to 1st century BCE in what is present-day India. Ayurveda was among one of the three oldest known forms of medicine, similar to Greek and Chinese medicine. The term "Ayurveda" is a Sanskrit word that embraces two facets, *Ayus* or *Ayur*, which refers to life principle, and *Veda*, the knowledge of how to live a long and healthy life (1). Like most ancient forms of medicine, Ayurveda is synonymous with holistic medicine and focuses on all facets of the individual for harmonious well-being. The primary means of treatment is by using phyto-active plant ingredients to cure various ailments. Ayurvedic practitioners have broad knowledge of plant biology and studied extensively the 1200 plants described for pharmacological applications (2). The medicinal practices are incredibly long and complex, and involve several aspects as described below (3):

1. Kayachikitsa (General Medicine)
2. Samhita (Basic Principles)
3. Vikriti Vigyan (Pathology)
4. Dravya Guna (Pharmacology)
5. Rasa Shastra (Pharmacy)
6. Shareer Kriya (Physiology)
7. Shalya Tantra (Surgery)
8. Kaumara Bhritya (Pediatrics)
9. Panchakarma (Bio-Purification Measures)

Ayurvedic therapeutic principles focus on treating a disease's cause and not just mitigating the symptom. In addition, the ideologies of Ayurveda focus on developing customized medicine and therapy for each individual, as opposed to mass-produced pharmaceutics practiced in western medicine. This is accomplished by creating a unique assessment for each individual based on body type, mainly categorized as "doshas" or basic energy types. There are three main energy types as described below (4):

- **Vata –** (air) energy that controls bodily functions associated with motion
- **Pitta –** (bile) energy that controls the body's metabolic systems
- **Kapha –** (phlegm) energy that controls growth in the body

Ayurvedic texts describe each individual with basic energy types following the above-mentioned principles. Imbalance of energy occurs due to a variety of factors such as genetics, stress, and unhealthy diet (1, 4). Much of the practice of Ayurvedic medicine emphasizes the need to balance energy for longevity. One might argue that knowledge and practice of Ayurveda is one of the oldest pioneering philosophies of the "beauty from within" concept that is widely accepted globally by the present-day cosmetic and beauty industry. This topical treatment was augmented in combination with an oral supplement, much like the cosmetic market today.

4.1.4.12 INGREDIENTS APPROPRIATE FOR COSMETIC/TOPICAL USE

Dermatological therapy using Ayurvedic ingredients has been practiced extensively in South Asia since the origin of Ayurveda. "*Panchakarma*," or bio-purification, uses oil or water based extracts of Ayurvedic blends to address dermatological concerns. These customized blends were taken in conjunction with oral supplements and applied as poultices for daily applications. Ayurvedic herbs become commonplace in the Western world around the 19th century, coinciding with the end of British colonization of India. The Ayurvedic recipes consist of simple botanical extracts, standardized ingredients, or purified actives, and can be of water or alcohol extracts based on the claim of the product. Different preparations have been used in cosmetic formulation as an ingredient or found in liposomal preparation. Some ingredients are also formulated as nutritional supplements to work synergistically with topical products (5). A brief summary of compounds used for Ayurvedic practices is given in Table 1 (End of Chapter). The following section describes in detail the most commonly used Ayurvedics in the beauty and personal care industry.

Ayurvedic ingredients with antioxidant potential

The formation of reactive oxygen species (ROS) results in cellular aging at different levels (19). ROS can react with various cellular components like the DNA, proteins, lipids, and saccharides, causing significant damage. ROS are important signaling molecules as part of the normal cellular processes and play a vital role in signaling and cellular cascades. Due to the exposure from the environmental insults (pollution, UV, stress, and smoking) the levels of ROS can increase dramatically and be a major factor contributing to aging. Skin, being the primary defense against environmental assault, is further damaged by ROS generation. Chronic exposure to ROS results in decline or even loss of skin's normal function. Damages, which can happen at different levels, include: RNA/DNA damages, impaired

lipid homeostasis, cellular inflammation, and oxidation of proteins and lipids. All of which lead to premature aging (19).

Almost all cells have endogenous protection systems, mostly in the form of enzymes to mitigate and convert the reactive singlet oxygen, the most important enzyme being *superoxide dismutase*. Another approach is to protect human skin by the use of antioxidants from herbs. Several Ayurvedic herbs that have found success in the cosmetic industry are primarily of interest for their antioxidant benefits (7). It has been well documented scientifically that folkloric medicine, particularly Ayurvedic medicine derived from plant extracts, has significant benefits in mitigating exposure to ROS.

The most successfully used Ayurvedic antioxidants include Amla (*Phyllanthus emblica*), Ashwagandha (*Withania somnifera*) Guduchi (*Tinospora cordiofolia*), Vidarikanda (*Pueraria tuberosa*) and Yashtimadhu (*Glycyrrhiza glabra*). These botanicals have rich sources of Vitamin C, phenolic acids, bio-flavonoids that act as strong anti-oxidants (7).

Amla (*Phyllanthus emblica*), a well-studied Ayurvedic botanical, is one of the richest known sources of Vitamin C. It also has high amounts of tannins, which not only have antioxidant benefits but is also anti-inflammatory in its effects. The active components of Amla are primarily gallic acid and ellagic acid. Amla has been used successfully formulated in cosmetic formulations to mitigate photo-damage as a result of UVA and UVB exposure to skin (7).

Ayurvedic ingredients with anti-inflammatory potential

Inflammation is part of a complex cellular response involving various cellular retaliators and multifaceted, interrelated biological processes (20). Most commonly, the inflammation stage is characterized as acute or chronic, based on severity of the inflammatory response. A variety of factors can trigger inflammation, not limited to environmental effects, stress, and infection (20). Figure 2 illustrates the inflammatory cascade in skin triggered by exposure of environmental stressors such as UVA or UVB and demonstrates the direct link of inflammation and skin aging processes, particularly with regard to breakdown of several critical extracellular matrix proteins such as collagen and elastin, and an increase in matrix metallo-proteases. In addition, a direct cause of inflammation is the impaired stratum corneum function of the skin. Stratum corneum plays a critical role in maintaining optimum function and barrier homeostasis. In addition, ROS generated by either acute or chronic exposure to various environmental pollutants also increase the inflammation response in skin and leads to premature aging (Figure 1).

Figure 1: Inflammatory cascade triggered by reactive oxygen species (ROS)

The most commonly prescribed anti-inflammatory medicine for is Aspirin, a nonsteroidal anti-inflammatory drug. For topical applications, the use of standardized and purified plant-derived compounds has proven to be successful. Figure 2 lists the purified compounds from Ayurvedic herbs used for cosmetic and therapeutic applications.

Clofibrate

Bakuchiol

Shatavarin-1

Himachalol

(1S,6R)-γ-himachalene **Guggulsterone-Z and Guggulsterone-E**

Figure 2: Chemical structure of ingredients used in ayurvedic practices

An example of an Ayurvedic plant studied extensively by scientists all over the world is turmeric. Turmeric a well-known Ayurvedic herb that has been used for millennia as part of the South Asian diet and is ascribed with anti-inflammatory and antiseptic benefits. Presently noteworthy research is being done with a purified secondary metabolite from turmeric, which has been identified as curcumin (8). In particular, curcuminoids have the ability to suppress certain cancers. For cosmetic use, curcuminoids act as a strong anti-inflammatory and modulate the expression of key inflammatory mediators such as TNFα, NFkB, COX2, and IL1 (9). Also, curcuminoids have the ability to protect extracellular matrix proteins such as collagen, elastin, and inhibitor of metalloproteinases when tested in skin-equivalent models (10). In summary, curcuminoids have the ability to be multifunctional, capable of mitigating the effects of free radicals and reducing inflammation, which makes this ingredient attractive to the cosmetic market.

Other noteworthy Ayurvedic ingredients with anti-inflammatory benefits include Bhrami (*Bacopa monnieri*), Bhrinjraj (*Eclipta alba; Eclipta erecta*), and Chirata (*Swertia chirata*).

Ayurvedic ingredients with antimicrobial potential

Modulating infection and regulating microbial consortia are of considerable interest for the cosmetic and beauty industry. Two of the most commonly occurring disease states, *acne* and *dandruff*, are a direct result of microbial infection. In the case of acne, the pathogenic microorganism is *Propionibacteria acnes*, while *Malassezia furfur* is primarily responsible for infecting the scalp and causing dandruff (11, 12). In addition, antimicrobial compounds are of huge interest for maintaining the integrity of cosmetic formulation as robust preservatives. There is enough evidence that Ayurvedic botanicals and blends have significant effect on controlling microbial population (13).

The bark of Neem (*Azadirachta indica A. Juss*) has been well documented for its antimicrobial potential, particularly in applications for oral care (14, 15). Neem plant has been the focus of several interdisciplinary research efforts for therapeutic applications worldwide. Over 100 active-compounds from Neem have been purified, and the biological activity associated with these compounds focus on skin care, oral care, and dental care applications (15). In fact, studies have demonstrated that Neem extracts are effective to control most common pathogenic microbes such as *Bacillus subtilis*, *Staphylococcus aureus*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Candida albicans*, and *Aspergillus niger* (16).

Current research focuses on developing blends of Ayurvedic plant extracts and identifying the antimicrobial efficacy in standardized tests for therapeutic benefits. An example of a blend of Ayurvedic herbs is Triphala, a combination of three plants Haritaki (*Terminalia chebula*), Bibhitaka (*Terminalia belerica*), and Amalaki (*Emblica officinalis*). Triphala is readily prescribed as a tonic to control microbial infection.

Much of the effort focuses on identifying the mode of action of these compounds to develop formulations for enhanced efficacy. Several double-blind clinical studies are being conducted to evaluate the efficacy of Ayurvedic products to mitigate disease states such as acne, dandruff, and others (17, 18).

4.1.4.13 CONCLUSION

There is a consensus among the scientific community globally for the need of a holistic, sustainable medicine. The global megatrends of aging population in particular support this need. Ayurvedic philosophies for customizable medicine tailored to individual need are also one of advantages. The challenge for Ayurvedic medicine is to have randomized and controlled efficacy evaluation for a large population. Considerable scientific effort is being focused on validating the efficacy of Ayurvedic medicine to support and broaden its applicability.

Consumer product companies are able to channel this ancient knowledge by offering Ayurvedic ingredients to the cosmetic market. Current Ayurvedic research focused on the development novel biological testing with standardized active constituents will help bridge the gap between Eastern philosophies and Western medicine.

As the cosmetic industry navigates towards sustainable and natural preservatives, Ayurvedic ingredients could be of high-value with well-established efficacy. The medicinal benefit of Ayurvedics will open up for global application.

TABLE 1

Common Name	Latin name	Part used	Mode of action	Claim
Chakund; Pumar; Panwar	*Chrozophora prostrata*	Seeds	Anti-inflammatory action	Skin inflammation
Neelkanthi	*Sphaeranthus indicus in combination with Grewia sp.*	Leaves and Tender branches	Anti-inflammatory	Dermatitis
Bakra; Jamrasi	*Elaeodendron glancnnl*	Leaves	Anti-inflammatory	Eczema
Gular	*Ficus glomerata, Roxb.*	Bark and Leaves	Anti-irritant	Eczema
Chameli	*Lawsonia inermis*	Leaves	Anti-irritant	Eczema
Kamila; babchi	*Psoralea corylifolia (Babchi)*	seeds		Dermatitis and rheumatic joints
Ashwa-gandha	*Withania Somnifera*	Root	Antioxidant and T-cell activation	Anti-aging
Guduchi	*Tinospora cordifolia*	Leaf and stem	Anti-inflammatory, antimicrobial	Anti-aging
Neem	*Azadirachta indica, A. Juss.*	Leaf and stem	Antimicrobial, anti-inflammatory	Skin care and oral care
Amla	*Phyllanthus Emblica*	Leaf, stem and fruit	Antioxidant, anti-inflammatory	Skin care and oral tonic
Guduchi	*Tinospora Cordiofolia*	Leaf and stem	Antioxidant, anti-inflammatory	Anti-aging
Vidarikanda	*Pueraria Tuberosa*	Leaf and fruit	Antioxidant, anti-inflammatory	Anti-aging
Yashti-madhu	*Glycyrrhiza Glabra*	Root	Antioxidant, anti-inflammatory	Anti-aging
Bhrami	*Bacopa monnieri*	Root	Anti-inflammatory	Anti-aging
Bhrinjraj	*Eclipta alba; Eclipta erecta*	Root, stem	Anti-inflammatory	Hair and skin care
Chirata	*Swertia chirata*	Root	Anti-inflammatory	Anti-aging
Haritaki	*Terminalia chebula*	Fruit	Anti-inflammatory	Skin care and oral tonic
Bibhitaka	*Terminalia belerica*	Seeds	Anti-inflammatory, antioxidant	Hair growth stimulation

PROBIOTICS IN TOPICAL PERSONAL HEALTHCARE: A NEW UNDERSTANDING . . . A BRIGHT FUTURE

Donald R. Owen, Ph.D., President
Owen Biosciences Inc.
7053 Revenue Dr.
Baton Rouge, LA 70809

ABSTRACT

Probiotics are beginning to be employed more in topical skincare because of recent science indicating live organisms are not required to elicit a positive bioactive response. The individual molecules believed responsible and the possible mechanisms of actions are reviewed. Recent evidence that keratinocytes possess immune activity similar to bowel epithelial cells connects observed activity of both oral and topically applied probiotics.

4.1.4.21 INTRODUCTION

"Probiotic" is an old term with lots of definitions. The World Health Organization has one that is fairly standard: "Live microorganisms which when administered in adequate amounts confer a health benefit on the host." We have used probiotics internally for thousands of years. Once we knew microorganisms were involved, we assumed these "good" bugs helped protect us from "bad" bugs. We also ascertained that the mechanism of action had something to do with the digestive tract, as these were all taken orally.

The use of probiotics as additives in topical personal healthcare products has been restricted by the obvious apparent need for "live" organisms, and we did not have any knowledge of the mode of action. We are all aware of the numerous foods that purport to offer probiotic ingredients and benefits: yogurt, buttermilk, miso, sauerkraut, kefir, etc. Many of these foods have been around for possibly thousands of years. We knew the result but not the mechanism. We also learned long ago that certain bacteria and yeasts could provide both a preservation component and a health benefit and, critically, not produce pathology.

Over the years the following organisms have become considered probiotic:

Selected strains of *Lactobacillus including: acidophilus, casei lactis, Plantarum, reuteri, rhamnosus, and helveticus*
Selected strains of *Bifidobacterium*
(new genus for *Lactobacillus bifidus*)
Selected strains of *Saccharomyces boulardii*
Selected strains of *Streptococcus thermophilus*
An argument can be made for: Selected strains of brewers' yeast *Saccharomyces cerevisiae*

These fermented foods did not spoil as fast and seemed to make us less prone to illness. Later we would say these seemed to help our immune system in a direct manner. Most of these products also appeared to work whether the organism was still alive or had become inactivated (e.g., from low pH, ethanol level, or pasteurization).

This would imply that the first part of the WHO definition needs a little alteration: "Live or dead microorganisms which when administered in adequate

amounts confer a health benefit on the host." This is not unexpected, as we can use either live or dead viruses in a vaccine to confer immunity. At this point a preferred term would be Probiotic Derived Bioactive (PDB), assuming the isolated ingredient from the total organism could be shown to be bioactive—i.e., possess immune stimulating properties, anti-inflammatory properties, etc.

4.1.4.22 OVERVIEW

Many researchers over the years have demonstrated that numerous biomolecules can be isolated from probiotic organisms (11–21) that are immune-stimulatory without any pathological characteristics.

So it would appear you do not even need the intact dead organism but rather only a particular part of the organism to produce a PDB. This is interesting but still does not tell us how the body "sees" these molecules or how it knows they are foreign, and what it produces that helps our immune system. These derived probiotics were thus, at least partially, a function of the outer coating of these organisms—since the inner parts of the probiotic organism were not needed.

For about 70 years we have known and used Beta-1,3-D-glucans (see Figures #1 and 4) associated with nonpathological yeast cell walls, as nutraceuticals and skincare additives. In the 1940s Zymosan was isolated from yeast cell walls by Dr. Louis Pillemer and determined to have immunological stimulating properties. By the 1970s Dr. Nicholas DiLuzio at Tulane University had identified the active biomolecule as Beta-1,3-D-glucan, and its use in treating human cancer and other conditions had begun.

Numerous patents and scientific articles cite (1–6) the use of Beta 1-3 containing D-glucans for immune stimulation, etc. In skincare, the "Glucan Glow" was advertised even if we did not know the cause. Numerous manufacturers now offer Beta-1,3-D-glucans from different sources. In all cases, if the appropriate molecule is present the same stimulation is observed independent of the source.

As with all topical bioactives, the delivery system employed to apply the topical PDB is critical to efficacy. The Beta-1,3-D-glucans have been used for many years, yet only recently has quantitative Polymerase Chain Reaction (qPCR) technology allowed the actual *in vivo* testing of human host peptide upregulation by PDBs.

Figure 1. The complex nature of the yeast cell wall, which not only includes the Beta-1,3-D-glucans but also glycoproteins, which also have immune-stimulating potential. Many of the commercial Beta-glucan preparations have been treated to remove all but the Beta-glucans. This includes the removal of all proteins, which can produce antigenic or overstimulation of the immune system, resulting in negative responses.

Figure 2. Probiotic *Lactobacillus Acidophilus* Cell Wall

As can be seen in Figure 2, the Probiotic organism *Lactobacillus Acidophillus*, a lactic acid producing organisms responsible for yogurt and buttermilk, has several well-known molecules associated with immune stimulation such as lipoteichoic acid and peptidoglcans (17). These molecules also were isolated and demonstrated to elicit stimulation of various immune-related cells in cell culture.

What's the common mechanism tying these together? The story gets a little bit more complicated at this point. In the mid 1980s a breakthrough occurred with the discovery of the defensins (1–4). These powerful antimicrobial peptides were found to be produced by our epithelial cells. Whether these epithelial cells were in the trachea, bowel, or epidermis of skin, they all had the ability to produce these host defense peptides. This was the key; this is the first line of defense against foreign organism invasion. The human host defense antimicrobial peptides can kill any bacteria, yeast mold, or virus attempting to enter through our skin, nose, lungs, digestive trachea, vagina, urethra, or skin.

The next discovery in the mid 1990s determined the mechanism by which the defensins were produced. Pattern Recognition Receptors (PRR) were found on epithelial cells that "recognized" specific chemical components from bacteria, yeasts, viruses, etc. One category of these was given the name "Toll-Like Receptors" (TLR's), which when activated, directly caused the production of antimicrobial defensins. So far, about 11 have been characterized—although all their functions are not yet known. These toll-like receptors were found on all epithelia including the mouth and nasal cavity, as well as in keratinocytes and Langerhans cells found in skin.

This innate system does not require any previous exposure to the organism. Therefore, these molecules can directly attack new foreign organisms and appear to also stimulate cellular parts of the human immune system into a second-line macrophage immune defense. The defensins also have numerous secondary characteristics besides antimicrobial properties. The literature reports that in addition to the antimicrobial properties, both proliferative and anti-inflammatory properties have been observed.

In the case of B-glucans it was also discovered by Brown et al. (2003) that the surface receptor Dectin-1 was also needed for the full response to fungi. The response to the B-glucans in the fungi wall is the production of TNF (tumor necrosis factor) and the defensins.

Figure 4: Unusual Biomolecules Found in Pathological and Probiotic Microorganisms Not Common To Humans

We now have a basic picture of how this ancient defense system works. It evolved over millions of years to allow mammals a first line of defense—without the requirement of immune cells being present or acquired immunity to have formed. All the cells, which come in contact with the natural environment, were given the ability to respond to foreign life forms (i.e., bacteria, yeast, molds, and viruses). All our surfaces inside and outside are one big immune system.

The toll-like receptors and other PRRs have evolved to "see" biomolecules that are foreign to us. We do not produce these molecules within our bodies. These biomolecules are outlined in Figure 4 (11–21). Probiotics are nonpathological

microorganisms that produce these molecules yet do not produce pathological symptoms—they are nontoxic, benign microorganisms, which look like bad guys but are not. They stimulate the toll-like receptors but cause no harm.

Like so many discoveries, our ancestors learned by trial and observation how probiotics could stimulate this ancient defense system without producing an actual illness. We could produce topical, oral, vaginal, and nasal products that could stimulate the local immune system to directly combat bacteria yeasts and viruses without actually knowing the exact mechanism.

However, knowing the exact mechanism helps in the next step for formulating with probiotics: How do you determine *in vitro* what works and what doesn't? Knowing that the defensins are the agents produced now leads to the next technology. In the past, only small animal testing (Rosette Test) could determine if an ingredient activated the immune system, and it did not directly measure the defensins.

Companies such as Mattek in the United States and Skin Sensitive in Europe have developed epithelial cell models that mimic the lining of the oral and nasal cavities, which produce defensins when stimulated with the appropriate molecules outlined in Figure 3.

Figure 3: Components In Fungi, Bacteria and Viruses That Activate Defensin Production Via Toll-Like Receptors

Commercial ELISA can monitor the defensin levels in these cell cultures before and after applying the test candidates. The results are at least semi-quantitative and give direct evidence of the potential efficacy of a topical, oral, vaginal, or nasal probiotic ingredient. This allows a rapid, reasonably priced (at least for large companies) alternative to animal testing that gives unequivocal data as to probiotic ingredient efficacy for product formulation.

Numerous raw material suppliers have made various probiotic-derived ingredients available for many years. For obvious reasons most commercial skincare or nasal or oral care products cannot be based on live organisms, which may continue to expel gas or consume other components in the formulation. Therefore, we must either kill the organism and use the whole organism as the stimulant or fractionate the organism via mechanical, chemical, or enzymatic methods.

In reality all these methods are being employed to enhance the bioavailability of the critical molecules, which are associated with probiotic activity. In many cases one could not determine the particular effects of these without human or animal testing. This makes it very difficult as a formulator to choose an appropriate probiotic ingredient.

However, the use of newer *in vitro* analytical technologies described previously allow these ingredients to be classified as true Probiotic Derived Bioactives. While the Beta-1,3-D-glucans have been the primary PDBs, numerous INCI-named ingredients are appearing in products with the scientific names of one or more of the organisms listed on the first page followed by "ferment," "extract," or "lysate" or a combination of these terms.

4.1.4.23 CONCLUSION

With the advent of testing biotechnology, the future is bright for probiotic ingredients and especially Probiotic Derived Bioactives. Being natural, with the capability of being certified organic in many cases, probiotic ingredients offer safe, green, and effective ingredients for the future. Aging is the loss of the ability to repair and maintain a healthy immune system. The ability to stimulate immunity and self-repair is a dream as old as probiotics. Yet the discovery that the defensins are overproduced in certain conditions, such as psoriasis, indicates that not all topical probiotic formulations are suitable for all consumers.

ABSTRACT

Historically, fermentation is defined as a natural process of converting complex carbohydrates into alcohols using bacteria or yeast. The use of fermentation for food precedes human history. Evidence of traditional wine and beer fermentation with yeast has been documented since 3000 BCE. Since the discovery of antibiotics by fungi in the 1920s, biotransformation of ingredients via fermentation has been explored for pharmaceutical applications. Fermentation and cell culture encompass a wide range of organisms including bacteria, fungi, plants, algae, and mammalian cells. Harnessing the power of biotransformation of organisms has been exploited for a multitude of industrial benefits including pharmaceutical, nutritional, bio-energy, and cosmetic applications. The biotransformation techniques employed for cosmetic and personal care traditionally focus on natural methodologies using safe microbes and plants. In addition, much of the process of fermentation and cell culture can be done in a controlled environment and elicited to express secondary metabolites and novel bioactive ingredients of interest. These ingredients expressed during fermentation can be difficult to isolate, and not found in nature in significant quantities. Therefore, fermentation and cell culture become sustainable means of producing unique ingredients with tremendous potential for personal care applications. For example, cell cultures of rare and economically challenged plants are a sustainable means to express important bioactive components such as carotenoids and flavonoids. Biofermentation and plant-tissue culture are definitely more economical and sustainable compared to extracting carotenoids and flavonoids from field-grown plants. Current industrial practices for personal care

focus on exploring novel extracts and components generated by biotransformation that are both natural and recombinant. These novel ingredients can be peptides, proteineaceous extracts, enzymes, small molecules, and phytoactive components. The following section focuses on describing the novel ingredients generated from biofermentation of organisms (microbes, plants, and algae). The section will discuss the mode of action and efficacy of these novel ingredients, then applications in the personal care industry. The section will conclude with the future outlook for bioactives in personal care generated by fermentation and cell culture.

4.1.4.31 RISE OF GREEN AND SUSTAINABLE COSMETIC INGREDIENTS FROM FERMENTATION

Fermentation-based products have a long history of use for cosmetics and beauty product applications. Whether it is the application of yogurt for scalp health, applying leftover grape-musts for skin care, or the use of fermented foods for beautification, the benefits of fermentation-based ingredients transcend cultures and geographies. Historically, most of the fermented products used for cosmetic mimic the nutritional diet referenced in a particular geographic region. The combination of fermentation and folkloric botanicals was often explored for enhanced benefit for health and beauty with continued success. The scientific community of consumer products realized the true potential of exploiting organisms for creating the next generation of ingredients for consumer products.

The focus of biotransformation efforts of the 19th and 20th century capitalized on the diversity of organism species available for fermentation. Fermentation efforts included a wide variety of bacterial species, yeasts, fungi, algae, plants, and unique organisms found in extreme environments (extremophiles). Coupled with the advances in the field of biotechnology for pharmaceuticals and drug discovery, the advent of using organisms (in particular microorganisms) as “biological factories” allowed scientists to generate novel compounds for beauty and wellness.

The essence of fermentation is the biotransformation of simple nutrients (sugars) to create novel compounds (secondary metabolites, bioactive compounds, vitamins, enzymes, antibiotics, peptides, and growth factors, etc.). The most commonly used fermentation and cell-culture applications for cosmetic applications broadly follow the principles of "submerged" fermentation and "solid-state" fermentation methods. Submerged fermentation is the fermentation using liquid media in an enclosed tank (typically made of stainless steel). In this type of fermentation, the media are utilized relatively quickly and active compounds are typically secreted in the media or can be extracted from the organisms (13, 16). The advantage of using submerged fermentation allows organisms that require high nutrients to grow robustly, and the purification of products is relatively easily. In solid-state fermentation, the nutrients utilized are carbon-rich raw materials (such as bran, paper pulp), which are utilized slowly. During solid-state fermentation the breakdown of nutrients takes place at a slower rate and the extraction process of involves multiple steps. The advantage of solid-state fermentation is the ability to recycle the nutrient source, therefore enabling a sustainable process (10, 13, 16). Solid-state fermentation is very common for fungal organisms and in utilizing food-waste biomass for the purposes of generating high-value compounds. The general schematic of a solid-state and submerged fermentation is shown in Figure 1. Recent advances in chemical engineering focus on modifying either the submerged fermenter or solid-state fermenter for most applications commonly used in cosmetic and consumer product industry (examples include air-lift bioreactors for algae, adapted with specific light sources; bioreactors with detailed air controls and mixing targeted for plant cell culture).

Schematic of fermenter typically used for solid-state fermentation

Schematic of fermenter typically used for solid-state fermentation

Figure 1: Solid-state and submerged fermentation examples (10):

For cosmetic and topical applications, fermentation and cell culture of a variety of organisms have been explored broadly. The most commonly utilized microorganisms are inspired by the nutritional and food industries, namely *Saccharomyces cerevisiae* (brewer's yeast) and *Lactobacillus sp.* (probiotic microorganisms). In addition, fungal species such *as Aspergillus niger* and *Aspergillus oryaze* (mold used for Koji rice fermentation) are well-developed fermentation vehicles. Algal cultures from macroalgae (kelp) to microalgae such as *Spirulina sp.* and *Ulkenia sp.* have been fermented in the bioreactor for specific secondary metabolites. Lastly, plant meristem cultures or the ability to harvest a broad variety of plant stem cells has garnered much success in cosmetic formulations. Furthermore, small-molecule fermentation of compounds such as resveratrol and other polyphenols have shown to be beneficial in cosmetic formulations and are bridging the gap between nutrition and personal care. Recombinant techniques have been employed to genetically modify organisms for the sustained expression of very specific secondary metabolites and compounds. It is also important to note that much of the work done in the area of fermentation and biotechnology incorporates multiple organisms and plant-based biomass.

The use of "stressed" lysates in cosmetic products is well established, and it has been demonstrated that these derivatives can help accelerate potential skin care activity in skin (7). For example, it has been found that organisms such as *Saccharomyces cerevisiae* and plant-cell cultures such as red rice callus culture can be grown in a bioreactor in the presence of external stresses. The response of organisms to external stresses, such as heat shock, peroxides, and ultraviolet light, is to provide enhanced production of novel active compounds that could have potential benefits for topical applications (1, 4). Figure 2 describes the various criteria that can be manipulated for fermentation of organisms. Current research also suggests that "dual fermentation," the ability to grow multiple organisms simultaneously for bioactive expression, has potential anti-aging benefits.

Figure 2: Factors influencing fermentation of ingredients for cosmetic and beauty products

In general, safety of the organisms is paramount for commercial success and market acceptance. The fermentation products can range from crude extracts, mixtures, and standardized active ingredients, to highly pure compounds (>99% purity). The success of biotransformation of organisms and the rise of fermentation can be attributed to several factors (11):

I. Biological diversity of species
II. Ability of organisms to express exclusive compounds that would otherwise be unavailable
III. Bioprocess conditions in a fermenter, allowing flexibility and controlled processing
IV. Ability to create stress-environments for organism, exposure by manipulating bioprocessing parameters
V. Technologies enabling expression of large quantities of desired active ingredients without the need to harvest large areas of biomass
VI. Enabling utilization of waste biomass to generate new compounds
VII. Reduced waste generation by using microorganism as the factory compared to significant amount of toxic byproducts made with chemical synthesis.
VIII. Chemical engineering, molecular biology, and microbiology advances allowing the scalability of several organisms from benchtop scale to industrial applications

4.1.4.32 THE IMPACT ON THE ENVIRONMENT

The natural trend in cosmetic industry has become a mainstay in consumer-product innovation. Consumer-product companies such as L'Oréal, Procter and Gamble, and Johnson and Johnson are evaluating every aspect of a product from packaging, supply chain, to manufacturing (Unilever, 20). In recent years raw material manufacturers are embracing fermentation as a way to ensure sustainable production of green ingredients for cosmetics and consumer-product applications. The market need for bio-based ingredients for cosmetic applications are captured in Table 1. It is estimated that a growth in the number of applications reaching commercial-scale production using fermentation could reach revenues up to €153bn by 2012 (21).

Table 1: Biotechnology options for cosmetic ingredients (21)

Polymer	Market (USD Billion)	Bio-based natural option
Polyurathene	~27	Soy based polyols
Polyester resins	~13	Maleic acid from succinic anhydride (manufactured by fermentation)
Nylon 6	~13	Caprolactam by fermentation
Acrylonite butadiene styrene	~11	Butadiene by succinic acid

The advantages of using biotechnologies versus conventional chemistries are enormous, based on industry's best practices for ingredients such as succinic acid, propanediol, hyaluronic acid, and others. The advantages of biotechnological innovation using fermentation to generate novel compounds compared to traditional chemistries are several (12).

I. Environmental benefits
   - Positive impact on CO_2 emissions
   - Ability to use renewable biomass waste generated from agriculture
   - Limited use of fossil fuels for manufacturing
   - Limits the need for pesticides and herbicides (particularly applicable for plant-cell culture)

II. Novelty of bioactive compounds via fermentation
   - Easy to generate significant quantities of novel ingredients
   - Prevents depletion of wild-biomass that may be scarce
   - Enables growth under conditions otherwise unattainable
   - Higher concentration of active components
   - Opens frontier to new active components
   - Easier way to procure uniform ingredients

4.1.4.33 ACTIVITY IN COSMETICS

Historically, the popularity of use of fermentation-based products in skin and hair care applications resonated with two microorganisms, *Saccharomyces cerevisiae* and *Lactobacillus sp*. Traditionally, live yeast cell derivatives (LYCD) from the yeast *Saccharomyces cerevisiae* have found the greatest use in personal care applications (1). The reason for this success is because *Saccharomyces cerevisiae* is a well-known, safe microorganism that has found use in multiple industrial applications such as beer brewing and baking. The organism is easy to grow and products can be isolated with relative ease; although color and odor control are key challenges in product development. For example, the application of lysates derived from *Saccharomyces cerevisiae* have shown to have an effect in increasing tissue respiration and accelerated wound healing (2, 4). In addition, the peptide fractions derived from yeast extracts can help stimulate skin-cell renewal and cell turnover through increased metabolic activity in the growing skin layers (14). Extracts from *Lactobacillus sp*. have significant applications in skincare such as the expression of beta-defensin production for anti-aging benefits (17). The extraction of standardized lactic acid from the fermentation of *Lactobacillus sp*. shows promise in skin-lightening benefits when tested on *in vitro* skin-equivalent models. The expression of bacteriocin peptides (short-chain antimicrobial peptides) is currently used as a management of *acne* (10, 14).

Numerous compounds from marine algal extracts have gained much importance for cosmetic applications due to its success in skin care applications. Marine algal compounds such as phlorotannins, sulfated polysaccharides, and tyrosinase inhibitors have shown applications towards a variety of skin-related topical formulations. *In vitro* studies on the extract from marine alga *Corallina pilulifera* have revealed the ability to prevent UV-induced oxidative stress and also the expressions of matrix metalloproteinase (MMPs) -2 and matrix metalloproteinase-9 in human dermal fibroblast cells (19). . Fucoxanthin isolated from *Laminaria japonica* has been reported to suppress tyrosinase activity suggesting broader applications in skin lightening (Figure 3). It is well documented that photo-damage to human skin by UV radiation leads to significant skin damage and ultimately premature aging. Skin damage by oxidants may lead to increasing MMPs expression and collagen degradation. Extracts of *Chlorella* have been shown to play some biochemical functions as well as *in vitro* inhibition of MMP1 activity (15). Micro-algae *species (Ulkenia sp.)* are well known for its ability to produce important lipids and the administration of the microalgae extracts have shown to significantly influence the effect of skin lipid synthesis (particularly cholesterol).

Figure 3: Tyrosinase inhibitors from algal extracts for potential skin-lightening applications (19)

Plant-cell cultures (meristem) are refined extracts of a selected plant and can be used for sustainable production of high-value compounds (3, 5). Red rice meristem extracts when used in cosmetic formulation suggest influencing epigenetic factors of aging, by influencing the (CPG promoter sequence) pro-collagen 1 and dermatopontin expression *in vitro.* In particular the red rice callus culture extracts are shown to improve Procollagen-1 and dermatopontin, which are extracellular proteins present in skin that deteriorates as we age. *Malus domestica* (apple) meristem cultures have shown promise in improving longevity of skin stem cells by delaying senescence of essential cells as a means to combat chronological aging. Influencing these proteins can have a noteworthy anti-aging effect and therefore is suitable for a variety of cosmetic applications. Plant-cell culture can also be a sustainable means to cultivate high-value compounds such as carotenoids and phytochemicals for skin and hair care applications. Figure 4 describes various plant-derived high-value compounds typically used in cosmetic formulations. One such group of high-value compounds are flavonoids (over 5000 plant-derived compounds with a flavane nucleus containing at least two benzene rings). Flavonoids can be extracted from several plant-cell cultures and have been reported in free radical scavengers; they are UVA absorbent, cyto-protective, and anti-inflammatory. They are also said to inhibit DNA damage and to affect cellular signaling pathways. Predominant dietary flavonoids include isorhamnetin, catechin, kaempferol, epicatechin, quercetin, and epigallocatechin-3-gallate (EGCG) (Figure 4) (5, 6, 22).

Figure 4: Chemical structure of high-value compounds obtained from plants (5)

Recombinant technologies are often exploited for the expression of specific peptides for cosmetic applications. Depending on the size of the peptides, there have been documented scientific benefits of using peptides in skin care formulations ranging from repressing the up-regulation of MMP-1 by skin fibroblasts (tetra-peptides), inhibiting tyrosinase (for skin lightening), or improving the function of skins structure by influencing TGF_{β}, (tri-peptides and their derivatives) (7, 22, 23). It would be remiss not to capture the significant contributions of recombinant technologies (genetically modified organisms) in the cosmetic and OTC realm. A good example is the successful commercialization of hyaluronic acid (traditionally found in rooster combs) in recombinant bacterial systems, enabling consistent large-scale production of an essential molecule for skin aging (18).

CONCLUSIONS

There remains a strong need for fermentation-based innovation as a solution to develop new active ingredients for cosmetic applications that are sourced sustainably. The popularity of fermentation-based products in the consumer-product arena is primarily a combination of three factors—namely safety, efficacy, and cost competitiveness. There is a consensus among the scientific community globally for the need of biotechnology-based ingredients whether from microorganisms, algae, or plants as molecular toolkits to generate new products. The market need is to develop products that are effective as well as green. Organizations should choose the biotechnology programs judiciously, based on market need and technology capabilities. The continued success of biotechnology will depend on demonstrating safety of ingredients from fermentation, public acceptance of such technologies, and continued investment in technology innovations to support long-term growth and value creation.

ABSTRACT

Today both consumers and manufacturers are looking for "greener alternatives" for use in cosmetic and personal care products. Infact, the herbal or natural-based cosmetics are one of the fastest-developing segments in the personal care segment. Major cosmetic brands are shifting towards incorporating natural compounds in their products and consumers can find ever-growing choices in "green" cosmetics.

Use of botanicals in skin or personal care products is not new; they have been used in cosmetics for centuries. In Ayurveda, the Indian traditional medicinal system, which is heavily based on botanicals, there are several examples of plant-derived products for alleviating skin problems or enhancing the skin beauty.

In many instances, modern science has provided the scientific evidence for the activity of botanicals. Structural elucidation using the latest technology has helped to identify the active phytochemicals present in such botanicals and understand their mechanism of action. Botanical extracts are no longer the crude extracts used in the traditional system, but have evolved into highly pure and standardized extracts, their efficacy established with modern cell- and enzyme-based assays.

In the present chapter we look into various key elements that are involved in developing botanicals as cosmeceutical actives. We also describe different extraction techniques that are commercially available for obtaining the extracts of choice, and the role of standardization in developing these botanicals extracts as cosmeceuticals with consistent quality and efficacy. We also would present examples of multifunctional botanicals with focus on their activities, standardization, and applications in cosmetics, along with any clinical study done on them. Apart from this, we discuss the very important subject of sustainability of natural resources for use in cosmeceuticals.

4.1.5.1 INTRODUCTION

Today we live in the age of green consumerism, and the personal care market is no different. Over the last one decade, the natural cosmetic market has shown tremendous growth and has been the fastest-developing segment in the personal care industry. In this consumer-driven market, the shift towards natural cosmetics can also be seen from the fact that many major cosmetics companies are now opening up for including natural products in their product line. The use of natural products in beauty and makeup is not new; examples of it can be seen in several civilizations. Use of oils such as thyme and rosemary on skin by Egyptians is well depicted hieroglyphically. Japanese used safflowers as pigments for rouge and lip makeup for ages (www.jcia.org), and in Indian culture examples of natural cosmetics such as dyeing hair with henna are well known (Auboyer 2002). The following sections are dedicated to discussion on the natural actives or natural cosmeceutical actives.

4.1.5.2 NATURAL AND NATURALLY DERIVED ACTIVES

Though definitions may vary for natural and naturally derived actives, it is important to understand the difference between naturally occurring and naturally derived cosmeceutical actives. Naturally occurring compounds when provided in

their natural form can be called natural products; hence epigallocatechin gallate when provided in an extract can be considered a natural active.

On the other hand, naturally derived actives do not occur in nature, but can be synthesized from naturally occurring sources. Examples of such compounds will be discussed in a later part of this chapter.

4.1.5.3 EXTRACTION TECHNIQUES

Since the natural compounds exist in a natural matrix of plant tissues and cells along with thousands of other coexisting compounds, to use them in conventional topical formulations it is important to extract them selectively from their natural matrix and purify them. These natural compounds may be present in certain parts of plant or herbal material, such as leaves, rhizomes, fruits, bark, or heartwood. For extraction of raw material, the process should be carefully chosen. The main requirements of the extraction process are:

a. Should be compatible with the plant material
b. Should be capable of selectively extracting and purifying the compound
c. Should be environmentally friendly
d. Should not be degenerative to compound or plant material
e. Should be economically feasible

Based on the raw material, there are various extraction processes that are commonly used in industry. Some of the major extraction processes are discussed below.

(1) Solvent extraction process
(2) Freeze-drying process
(3) Supercritical fluid extraction process

Solvent extraction is the most commonly used process. This process uses a variety of solvents, from a polar to nonpolar range, based on the particular compound of interest. Ethanol, methanol, isopropyl alcohol, ethyl acetate, acetone, and hexane are commonly used for extraction in industrial quantities. These solvents extract selective compounds based on the polarity of the compounds, thus enriching them in the extract.

The freeze-drying process is used for more sensitive and heat-labile compounds, which cannot withstand high-temperature treatment for long period of times, as in the case of solvent-extraction process. Freeze-drying is carried out in three steps: (1) freezing, (2) primary drying, and (3) secondary drying. The temperature of the freezing step is maintained at –40°C, converting most of the water present in the raw material into ice. Primary and secondary drying is carried out at elevated temperature to remove most of the unfrozen water (SM Patel 2010).

Supercritical fluid extraction is a process where supercritical fluids such as carbon dioxide is used for extracting the material from a solid or liquid matrix. Carbon

dioxide is the most commonly used supercritical fluid in this type of extraction. Carbon dioxide at its critical temperature (31°C) and critical pressure (74 Bars) tends to behave both like a gas and a liquid. This type of extraction process requires an expensive setup and has limitations in the of types of raw material that can be extracted. Carbon dioxide, being a nonpolar itself, can extract compounds of similar polarity and is thus limited to nonpolar compounds present in oils and oleoresins. Use of modifiers can to some extent increase the range of compounds that can be extracted (He et al. 2005).

4.1.5.4 ROLE OF STANDARDIZATION

One thing that can decide the efficacy of a product is the amount of active inside; thus it is of prime importance that the product should be properly formulated to contain the required amount of active inside. In natural products where the extracts may contain several hundred compounds present in macro- to micro- and even in nano-quantities, it is of utmost importance to have a proper standardization of the extract. Standardization is defined by the American Herbal Product Association (AHPA) as "the body of information and controls necessary to produce materials of reasonable consistency. This is achieved through minimizing the inherent variation of natural product composition through the quality assurance practices applied to agricultural and manufacturing processes" (Gaedcke et al. 2003). The first step in standardization of an extract is identification of the active compound. Once the active component is identified, it can be used as a reference for the quality of an extract and also its dosage levels for formulation. For a good batch-to-batch efficacy, the product should contain the same amount of actives. One of the major tasks in natural product formulation is preparation of a reference library of compounds that are used for standardizing an extract.

Apart from consistency in quality, standardization also helps to preserve the authenticity of the natural extracts. Proper identification of the marker compounds and chemical fingerprinting of the extracts using the latest chromatographic tools help ensure that extracts provide the desired biological activity and are free from any adulterants.

4.1.5.5 MULTIFUNCTIONAL BOTANICALS

a. Saberry®

Saberry® is the trade name for the Indian gooseberry extract marketed by Sabinsa. Saberry® is standardized to 10% of the active compound Beta glucogallin. Indian gooseberry or Amla is regarded as a tonic herb or *rasayan* in Ayurveda. It is also known as a detoxifying herb and is used to correct the doshas in Ayurveda. Apart from its use in oral Ayurvedic formulations, Amla is also used in topical beauty

care. Amla oil is known to be one of the world's oldest natural hair conditioners. Amla fruits have also been studied for their skin-lightening activity and MMP-1 inhibitory activity.

Amla fruit were long considered a rich source of vitamin C, which also accounts for its high antioxidant activity. However, the studies carried out on Amla in the last few years have raised questions on the presence of ascorbic acid in the fruits.

In order to unfold the nutritional and cosmeceutical benefits of gooseberry, a proper identification of a valid biomarker was required to resolve the confusion and authenticate the extract. Extensive work done by the research group at Sabinsa using modern isolation and hyphenated techniques like HPLC, flash chromatography, and spectroscopic method LCMS and NMR led to the identification of biomarker compound Beta glucogallin (Figure 1).

Fig 1: Structure of Beta glucogallin

Amla extract biostandardized with Beta glucogallin revealed the true cosmeceutical potential of this superfruit from India (Majeed et al. 2009).

Cosmeceutical potential of Saberry® (Indian gooseberry extract)

Antioxidant Activity

Brunswick Labs in Wareham, MA evaluated the ORAC activity of Saberry® using state-of-the-art ORAC tests. The ORAC* assays—ORAC, HORAC, NORAC, SORAC, and SOAC—are validated tests to measure broad-spectrum antioxidant power. The ORAC activity is expressed in micromole standard per gram. ORAC analysis (Table 1) showed that Saberry® has excellent ORAC activity in hydrophilic media. As expressed in the table below, Saberry® showed combined ORAC activity of 3586 micromole Trolox Eq per gram.

ORAC Activity

ORAC Hydro (µmol TE/g)	ORAC Lipo (µmol TE/g)	ORAC Total (µmol TE/g)	HORAC (µmol CAE/g)	NORAC (µmol TE/g)	SORAC (Kunits SODeq/g)	SOAC (µmol VItE/g)
2678	4	2682	345	904	102	1351

Table 1: ORAC activity for Saberry®

ORAC* Activity or Oxygen Radical Absorbance Capacity is an assay to measure the antioxidant activity in biological samples. AOAC International recently approved the ORAC method as a first action official method for measuring antioxidants in foods. (http://www.aoac.org/News/AOAC_SPS-FAM-01042013-2.htm). The various ORAC activities mentioned above are part of the ORAC activity assay, namely, $ORAC_{hydro}$ measures the activity against peroxyl radicals in hydrophilic medium. $ORAC_{Lipo}$ measures the antioxidant activity against peroxyl radicals in lipophillic medium. HORAC measures the activity against hydroxyl free radicals, while NORAC measures the antioxidant activity against peroxynitrite radicals. SORAC measures activity against the superoxide free radicals, and SOAC measures the antioxidant activity against the singlet oxygen.

1. Skin-lightening activity

The skin-lightening activity of Saberry® Amla extract standardized with 10% Beta glucogallin was studied by the research group at Sabinsa Corporation using nonanimal test models. Saberry® was tested for its melanogenesis-inhibitory activity using B16 F1 melanoma cells. The melanin production in these melanoma cells is induced by α-MSH and cAMP cells in two different samples. These cells were then treated with varying concentration of Saberry over a period of nine days with test substance (Saberry®) treatment repeated at regular intervals for three days (Figures 2, 3).

The melanin thus produced in the cells was treated with 1N NaOH, and absorbance was read at 405 nm in a microplate reader. The study was carried out with comparison to kojic acid.

Saberry showed IC_{50} of 14μg/ml in both cAMP induced and α-MSH–induced melanogenesis inhibition. Kojic acid in the same test showed IC_{50} of 100μg/ml (Sami Labs Report 09-223).

Figure 2: Inhibition of camp-induced melanogenesis by Saberry® in B16 F1 mouse melanoma cells

Figure 3: Inhibition of α-MSH–induced melanogenesis by Saberry® in B16 F1 mouse melanoma cells

2. UVA and UVB protection by Amla extract

Amla extract is known for protecting the human dermal fibroblast cells against oxidative stress. The studies have shown its protective effect on human skin fibroblasts, especially for production of pro-collagen. In a study published in *J Ethnopharmacology* (2008), it was found that Amla extract stimulated the proliferation of fibroblasts and helped to induce the production of pro-collagen in a dose-dependent manner. Study also showed inhibition of MMP-1 enzymes from the fibroblast cells (Fuji et al. 2008).

MMP-1 or matrix metalloproteinase (MMP) is responsible for the dermal photo-aging in human skin. UV irradiation actually up-regulates the production of UV-induced collagenases such as MMP-1 from dermal fibroblast cells (Quan et al. 2010).

Scientists at Sabinsa studied the cell viability of Swiss 3T3 mouse fibroblast cells in the presence of UV exposure with and without Saberry®. The Swiss 3T3 mouse fibroblast cells were placed in a microplate and treated with varying concentrations of Saberry and exposed to 5J cm-2 UV dosage and 0.05J cm-2 UVB dosage. After the exposure, the cells were incubated in a CO_2 incubator for 48 hours and developed by NRU staining techniques to analyze the cell viability (Figure 4).

Saberry® showed IC_{50} of 14µg/ml for protection against UVA radiation and 42µg/ml against UVB radiation (Sami Labs Report 09-223).

Sami Labs Report: 09 223 Cosmeceutical potential of Saberry®

Figure 4: UV protection by Saberry® in Swiss 3T3 mouse fibroblast cells

Cosmeceutical applications of Saberry®

Saberry® is standardized with a unique biomarker—Beta glucogallin. It is a beige-colored extract and completely water soluble. It can be used in anti-aging formulation, skin lightening or skin fairness, and sun-protection formula. It is free from any preservative.

Formulation guidelines

1. Solubilize Saberry® before adding it to emulsions below 40°C.
2. It forms a hazy solution with water (1:10) at 40°C.
3. Maintain the pH of the formulation as slightly acidic (5.0–6.0).
4. Saberry® can be gelled using thickeners such as carbomer, acrylates copolymer, and lecithin.
5. Protect the finished product from direct exposure to light and heat and use opaque packing.

Suggested level of use

Skin-lightening formulations: 0.1–0.3% w/w

Anti-aging: 0.05–0.2% w/w

Suncare/ after suncare: 0.2–0.3% w/w

Depigmentation: 0.1–0.2% w/w

b. Ellagic acid (from pomegranate)

Ellagic acid (Figure 5) is a naturally occurring polyphenol present in a variety of plants such as cranberries, raspberries, walnuts, grapes, and pomegranates (Usta et al. 2013).

Figure 5: Ellagic acid

Pomegranate as a source of ellagic acid has been of much interest for both nutraceutical as well as cosmeceutical benefits. Pomegranate fruits have shown antioxidant properties due to the presence of ellagic acid, which is one of the main polyphenols in the pomegranate fruit (Bell et al. 2008). Ellagic acid has been shown to have anticarcinogenic, antioxidative, and anti-proliferative activities.

Skin-lightening activity

Ellagic acid has also been studied for its topical benefits. Ellagic acid, being a polyphenol, is able to interfere with oxidative steps in the melanin synthesis, which is catalyzed by the tyrosinase enzyme.

Furthermore, due to its antioxidant activity it can also scavenge the reactive oxygen species, which can also play important role in melanin synthesis (John et al. 2005). Another mechanism proposed for its skin-lightening activity is related to its higher affinity to copper present on the active site of the tyrosinase enzyme (Shimogaki et al. 2000), which catalyzes the oxidative conversion of tyrosine to dihydroxy-phenylalanine (DOPA) and further from DOPA to DOPA-quinone.

To understand the underlying mechanism of tyrosinase inhibition by ellagic acid, Shimogaki et al. studied tyrosinase inhibition by ellagic acid in the presence of copper. While the tyrosinase enzyme activity was reduced or inhibited in presence of ellagic acid, this was partially recovered following the addition of copper. This suggested that the ellagic acid inhibits the tyrosinase activity by affecting the copper present at the active site of the enzyme (Shimogaki et al. 2000).

By incubating the cells with ellagic acid in the presence of copper compounds, researchers were able to show that ellagic acid inhibits the tyrosinase activity by affecting the copper present at the active site of the enzyme.

UV-protective activity

In the animal study done by same group (Shimogaki et al.), the protective activity of ellagic acid against skin pigmentation induced by UV rays was studied and compared to kojic acid and arbutin.

The study was carried out on brownish guinea pigs, which were exposed to UV-B irradiation once a day for eight days on a shorn test site on their backs. The test substance (ellagic acid) was applied topically every day for six weeks. After the six weeks the animals were sacrificed and skin samples were studied. It was found that ellagic acid plays a key role in preventing skin pigmentation following UV irradiation. The melanin content of skin was found to be reduced with ellagic acid application, not only in the basal layer, but also in other layers such as the stratum spinosum, stratum granulaosum, and stratum corneum.

Comparative data showed that ellagic acid at 1% was more efficient than kojic acid and arbutin at same percentage in reducing pigmentation on the skin.

Cosmeceutical application of ellagic acid

Ellagic acid containing extracts can be used for skin lightening, for management of hyperpigmentation, UVB protection, and antioxidant activity. As ellagic acid is not soluble in water, solvents such as PEG 300 and BG can be used to dissolve the active in the formulation stages. Suggested level of use is 0.1–0.5%.

Quasi-drug status of ellagic acid in Japan

Ellagic acid is one of the approved quasi-drug ingredients for management of hyperpigmentation disorder in Japan. Skin-lightening quasi-drug is a category of cosmetics that can be regarded as functional cosmetics, and can prevent or improve hyperpigmentation disorders such as melasma and chloasma. Quasi-drugs require a premarket approval by Japanese ministry of Health, Labor and Welfare (MHLW) (Ando et al. 2010).

c. Tetrahydrocurcuminoids (Turmeric extract)

Figure 6: Structure of tetrahydrocurcumin

Tetrahydrocurcuminoids are the major metabolites of the naturally occurring curcuminoids in the turmeric rhizomes. The curcuminoids are the active compounds present in turmeric. curcuminoids have been focus of several research studies and clinical trials for their anti-inflammatory, anti-cancer, hepatoprotective, antioxidative activities etc. (Osawa 2007).

Curcuminoids have also been traditionally used on skin for skin fairness and for healing of wounds. Paste of turmeric and neem is used for ulcers and scabies (Phillip 2011, 2nd ed.). However, due to their dyeing nature, the use of curcumin or turmeric based topical products on skin is quite cumbersome. Application of curcumin on skin can lead to staining that may last for a couple of days, not ideal for conventional cosmetic application for Caucasian skin.

Scientists at Sabinsa found a novel way to introduce the goodness of curcumin/turmeric in conventional cosmetics without including the staining nature of the curcumin.

Tetrahydrocurcuminoids (Figure 6), as mentioned above, are the major metabolites of curcuminoids. Tetrahydrocurcumin is obtained by hydrogenation of the double bonds existing in the curcumin structure. Due to loss of conjugation in the structure (Figure 7), the tetrahydrocurcumin absorbs the light in UV area and appears white in color. Tetrahydrocurcumins are not only free from color, but also from staining nature of curcumin.

Figure 7: Conversion of curcumin to tetrahydrocurcumin

Tetrahydrocurcumin as an antioxidant

Tetrahydrocurcuminoids are obtained from curcuminoids, which are well known for their antioxidant activity, and hence the studies have been carried out to compare antioxidant activity of both curcumin and its metabolites—tetrahydrocurcuminoids. Studies carried out by Osawa et al. found that tetrahydrocurcumninoids had the strongest antioxidant activity among all the curcuminoids tested in different assay methods.

Osawa et al. selected curcumin, demethoxycurcumin, and bis-demethoxy curcumin and their corresponding hydrogenated tetrahydrocurcuminoids for comparison by using linoleic acid as substrate in an ethanol/water system. They also used *in vitro* systems such as rabbit erythrocyte membrane ghost and rat liver microsomes for determining the antioxidant activity of these compounds by measuring the TBARS (thiobarbituric acid reactive species) generated by the oxidants (Osawa et al. 1995).

DPPH Free Radical Scavenging activity

Free radical scavenging activity of tetrahydrocurcuminoids was determined using DPPH assay (diphenyl picril hydrazyl radicals). DPPH radicals show a decrease in absorbance due to their quenching by antioxidants.

Different concentrations of test substance are incubated with 0.1mM DPPH methanolic solution for 30 minutes. The reduction in absorbance of DPPH radicals is then studied at 516nm and scavenging activity is expressed as SC50.

Using the above method to determine the free radical scavenging activity, tetrahydrocurcuminoids was compared with resveratrol (95%). The results are given in the table below.

Tetrahydrocurcuminoids were found to have more than twice antioxidant activity than the resveratrol, the major polyphenols present in grapes skin and red wine (Sami Lab Test Report 201).

Product	**Scavenging Activity SC_{50}**
Tetrahydrocurcuminoids 95%	1.14
Resveratrol 95%	3.24

Table 2: DPPH free radical scavenging activity

Skin-lightening potential of tetrahydrocurcuminoids

In view of traditional use of turmeric on skin for increasing glow and radiance, tetrahydrocurcuminoids were evaluated for their skin-lightening potential using an enzyme-based method involving tyrosinase inhibition as well as an *in vitro* method using melanogenesis inhibition in B16 F1 mouse melanoma cells.

In the enzyme-based assay, tetrahydrocurcuminoid compared favorably to several other skin-lightening natural compounds such as kojic acid, vitamin C, and Arbutin (Sami Labs Report No. 09, 222). The table below gives the tyrosinase inhibition activity in terms of IC_{50} (Table 3).

Product	**Inhibition Capacity IC_{50}**
Tetrahydrocurcuminoids 95%	2.0
Kojic acid	3.0
Vitamin C	9.33
Arbutin	33.0

Table 3: Tyrosinase inhibition activity

In another test on skin-lightening potential using the B16F1 melanoma cells, tetrahydrocurcuminoids have shown great potential in reducing the conversion of tyrosine to L-DOPA and thus formation of melanin in the cells. The melanogenesis activity was compared with the kojic acid, vitamin C, and arbutin. In this cell-based assay (Sami Labs Report No. 09 222), tetrahydrocurcuminoids showed significantly better melanogenesis inhibition potential compared to kojic acid, vitamin C, and arbutin (Table 4).

Product	Melanogenesis Inhibition Capacity IC_{50}
Tetrahydrocurcuminoids 95%	3.5
Kojic acid	100
Vitamin C	25
Arbutin	100

Table 4: Melanogenesis inhibition activity

In another study done by researchers at Sabinsa, skin-lightening potential was compared with hydroquinone using melanogenesis inhibition model with B16F1 mouse melanoma cells. The results (table) showed that although the hydroquinone inhibits melanin more effectively, it was toxic at those levels. Due to its toxicity, hydroquinone use is restricted.

Conc. (mcg/ml)	*% inhibition of melanin*	
	THC CG	**Hydroquinone**
0.125	32	12
0.25	40	18
0.5	45	48
1	52	**toxic**
5	80	**toxic**
10	toxic	**toxic**

Table 5: Melanogenesis inhibition with toxicity

d. Sabiwhite® - 955 tetrahydrocurcumin extract

Sabiwhite® (INCI: Tetrahydrodiferuloylmethane) is a color-free natural extract derived from turmeric roots with proven luminosity-boosting and skin-lightening effects. It is an effective skin-lightening agent with multifunctional topical benefits and no sensitization side effects. SabiWhite® works on multiple targets that cause undesirable pigmentation, including free radicals, UV exposure, melanin production, aging, etc.

In vitro studies antioxidant studies on Sabiwhite®

1. Reactive oxygen species scavenging in Swiss 3T3 fibroblast cell line- IC_{50} 1.44µg/ml
2. ORAC Activity – 10,815µg/ml Trolox eq/g
3. HORAC Activity – 3,152µMol gallic acid eq/g

Clinical Study on SabiWhite®

In a randomized, double-blind, placebo-controlled comparative study—tetrahydrocurcumin (Majeed et al. 2010), the major metabolite in the tetrahydrocurcuminoids, was compared for its safety and efficacy against hydroquinone.

This study was carried out in the Philippines by the Research Institute for Tropical Medicine.

In this study Sabiwhite®, Sabinsa's brand for tetrahydrocurcumin, was compared with hydroquinone over 50 human subjects in a randomized, placebo-controlled four-week study. The concentration of H\hydroquinone was used at 4% while 0.25% of tetrahydrocurcumin was selected for comparison for safety as well as efficacy. The study was carried out in two phases. In Phase 1, the 48-hour IQ chamber closed patch test was carried out on 50 healthy subjects (aged 21–45). The subjects who developed no adverse reaction were included in Phase 2 of the clinical trial.

The Phase 2 trial was carried out as a randomized, double-blind placebo-controlled comparative study of 0.25% tetrahydrocurcumin (brand name Sabiwhite®) against 4% hydroquinone formulation for depigmenting activity.

The results showed that 0.25% tetrahydrocurcumin was more effective than 4% hydroquinone in reducing the pigmentation as demonstrated in the four-week trial. Further, the 0.25% THC showed 100% compliance with no patient dropout or any incidence of adverse reaction, while in the hydroquinone group 50% of the subjects developed an adverse reaction, thus demonstrating the benefits of THC as an effective and safe alternative to hydroquinone.

Cosmeceutical potential of tetrahydrocurcuminoid

Tetrahydrocurcuminoid is an off-white to cream-white powder; it can be used in skin lightening, fairness formulations, management of hyperpigmentation, and in age-defying products. The toxicity studies have shown no irritation potential on skin. *In vitro* dermal irritation studies have shown no irritation, while the ocular irritation studies have shown minimal irritation potential.

e. Cococin™ (Freeze-dried coconut water)

Cococin™ is freeze-dried extract of green coconut water. Coconut water is a liquid endosperm of *Cocos nucifera*. This endosperm is present in greatest amount in a green coconut. As the coconut matures, this liquid serves for growth of solid endosperm and the embryo. Coconut water or liquid endosperm serves as a natural reservoir of nutrients to promote the tissue growth. The coconut water in a green coconut is rich in proteins, amino acids, vitamins, and growth hormones essential to promote the tissue-growth minerals (Awua et al. 2011; Tulecke et al. 1961).

Coconut water is regarded as a reservoir of nutritious compounds present in the coconut. Traditionally it has been used as refreshing beverage replenishing the minerals lost from the body and has been often used as a natural electrolyte rehydration solution due to its isotonic nature. Coconut water is a quite popular ingredient in sports nutrition drinks with high potassium and low sodium content.

Manufacture of coconut water solids - Cococin™

Cococin™ is manufactured using the freeze-drying process. The young green coconuts are carefully selected and the liquid endosperm is collected from these coconuts. This liquid endosperm is then microfiltered to filter out any extraneous substance that could be introduced in the extraction process of endosperm from the coconut. The freeze-drying process under controlled conditions ensures that the coconut solids obtained from the process retain their biological activity. The amorphous nature of the freeze-dried material protects the protein components during pulverization and storage. During storage, the material transforms into the more stable crystalline state, which is also less hygroscopic (Majeed et al. 2007; U.S. Patent 7,300,682).

Applications

Apart from the nutritional benefits, coconut water has many potential cosmeceutical applications, where it can be used on skin as well for hair care. In the next few paragraphs we will discuss the potential applications of the coconut water (Cococin™) in hair care as well as skin care.

Cococin™ in hair care

Coconut water as mentioned previously is a reservoir for nutritious compounds, some of which promote cell and tissue growth. Cytokinins are one such plant-growth substance present in the endosperm of green coconut, which are involved in cell growth and differentiation (Kobayashi et al. 1995). In view of the role of coconut water solids in supporting cell growth, coconut water (Cococin) can be used in applications supporting the growth of human tissues such as hair follicles. Thus the potential use of Cococin can be found in hair-growth products such as hair gels, shampoos, conditioners, etc.

A study to evaluate the effect of Cococin™ on cell growth was carried out by the biological research group at Sabinsa (Sami Labs Report 208).

Cell proliferation enhancement by Cococin™ was studied by inflicting a wound over the fibroblast (Swiss 3T3) monolayer and fibroblast proliferation was monitored (Figure 8) in media containing varying concentrations of Cococin™.

Figure 8A: Control (Day 0)

Figure 8C: Cococin (Day 0)

Figure 8B: Control (Day 1)

Figure 8D: Cococin (Day 1)

Figure 8: Cell proliferation enhancement by Cococin™ in Swiss 3T3 fibroblast cell line

Results from the cell proliferation was observed and compared with fetal bovine serum. The comparative proliferation can be seen in the graph below (Figure 9).

Figure 9: Proliferation of fibroblasts using FBS- and Cococin-containing media

Study showed that the coconut water solids in Cococin™ support cell growth. Further, Cococin™ may be used in the application to support the growth of human tissues such as hair follicles. Cococin™ can be used in hair care formulations.

Cococin™ patents

U.S. patent (No. 7,300,682) The patent is titled "Method of preparation and use of coconut water in mammalian tissue nourishment growth and healthy maintenance." The patent covers the derivation process, composition, and intended uses of Sabinsa's branded ingredient Cococin™, a freeze-dried powder form of green coconut water.

Cococin™ is covered by **European patent (No. EP1341547)** for its process, composition, and use in the European market.

The newly patented SABERRY®+COCOCIN™ synergistic formulation protects dermal papilla cells from stress signals. Dermal papilla cell clusters are mesenchyme cells, which perform several important functions that include:

1. Being reservoirs of multi-potent stem cells, which are critical assets in the area of regenerative medicine;
2. Having the physical inductive influence on the cells of undifferentiated epidermis to push into the dermis as part of processes involved in skin appendage formation;
3. Acting as body's antidote mechanisms for preventing unwarranted inflammatory reactions; and
4. Producing useful antimicrobial proteins.

Cococin™ for skin care

As mentioned earlier, coconut water has extremely good rehydrating activity and hence can be used as a topical moisturizer and improves the skin elasticity and skin tone.

In an unpublished (22 female subjects, aged 20–35 years) double-blind placebo-controlled clinical study (Research Report Sami Labs Ltd 2005), 200mg of cream containing 1% coconut water solids (Cococin™) and other natural ingredients was applied daily for eight weeks on the left arm of each subject and cream base was applied on the corresponding area of the right arm to serve as control.

The reduction in skin roughness was evaluated with skin visiometer, and dermal elasticity was measured using a cutometer.

Results (Table 6) showed that treatment with cream containing Cococin™ significantly improved the skin elasticity, which was manifested in decreased skin roughness and improved skin tone. Thus coconut water solids in Cococin™ nurtures keratinous tissue and supports tissue integrity, thereby potentially inhibiting the appearance of signs of aging and the manifestation of wrinkles.

Figure 10: Change in elasticity on application of Cococin-containing cream

Cosmeceutical applications of Cococin™

Coconut water solids in Cococin nurture keratinous tissue and support tissue integrity, thereby potentially inhibiting the appearance of signs of aging and the manifestation of wrinkles.

Cococin can also be used in hair care for its hair-growth potential.

The recommended usage levels are 1–5%; it is completely dispersible in water.

f. ForsLean (*Coleus forskohlii* rhizomes)

Coleus forskohlii belongs to the family *Lamiaceae*. Coleus is one of the most versatile plants that grow in arid and semi-arid climates. It has been well known in Ayurveda, the traditional Indian medicine system, for treating conditions such as insomnia, intestinal spasm, heart and lung conditions, etc. (Schaneberg & Khan 2003). *Coleus forskohlii* is one of the species of coleus that is unique as it only contains the compound forskohlin. Forskohlin is a direct activator for adenylate cyclase, which is involved in generation of cyclic AMP (Shoback and Brown 1984), a secondary messenger that plays a key role in activation of lipase involved in breaking the fat. This has led to use of coleus in weight management. Sabinsa introduced patented coleus as a dietary supplement for weight management under the brand name of ForsLean®.

Coleus forskohlii roots are the main source of forskohlin. The roots, apart from forskohlin, are also rich source for coleus oil, which has good skin care activity.

Coleus oil

Coleus forskohlii contains an essential oil that has a spicy note; it can be used in cosmeceutical industry. The main component of the oil are 3-decanone, bornyl acetate, gamma eudesmol, and Beta-sesquiphellandrene (Paul, Radha, and Kumar 2013). The coleus oil can be extracted using a supercritical fluid-extract process. The rhizomes of *Coleus forskohlii* after sun drying are powdered and loaded in the extractor. Using carbon dioxide as the supercritical fluid, the rhizomes are extracted to give light-yellow-colored oil with a strong citrus odor. The oil is standardized with Alpha-pinene, Beta-pinene, bornyl acetate, and decanal. The coleus oil can be used as an antimicrobial ingredient and a perfumery ingredient, as it has a spicy, musky odor.

Antimicrobial activity of *Coleus forskohlii* oil

In house studies done at Sabinsa (Sami Labs Report 198) have shown that coleus oil is more effective than tea tree oil in inhibiting growth of the skin pathogens such as

-*Propionibacterium acnes* – Associated with acne on the skin

-*Staphylococcus aureus* – A bacterial strain found in infected wounds and skin eruptions, including acnes

-*Staphylococcus epidermis* – A bacterial strain occurring in a variety of opportunistic bacterial skin infections

In-house study data (Figure 11) at Sabinsa shows that coleus oil at 2% concentration is as effective as tea tree oil or clindamycin. Its aroma is also an advantage over the tea tree oil, as it does not require odor masking in the formulation.

Figure 11: Comparison of antimicrobial activity against *P acnes* between coleus oil, tea tree oil, and clindamycin.

The suggested level of use of coleus oil in skin care formulation is 5–10% and in aromatherapy or perfumery level can be 0.5–1.0%.

Patent on coleus oil

US patent 6,607,712 Majeed M., Prakash S.: Composition and methods containing an antimicrobial essential oil extracted from *Coleus forskohlii*.

Coleus extract 95% (containing 95% forskohlin)

The coleus rhizomes as mentioned earlier, apart from the oil are also a source of active component forskohlin. This compound is exclusively found in only *Coleus forskohlii* species. Forskohlin is a direct activator for adenylate cyclase, which is a transmembrane enzyme with key regulatory roles in some of the human tissues including fat cells. Sabinsa pioneer "ForsLean®" is a coleus extract standardized to the active compound forskohlin, which is a direct activator for secondary messenger (cAMP), this direct activation of cAMP takes place without activating the adrenergic receptors. This mechanism plays a key role in inducing lipolytic activity in fat cells without causing any unwanted side effects associated with activation of receptors as seen in the case of ephedra.

Topically the forskohlin extract can play a significant role in management of cellulite, due to its mechanism of action as explained above. Cellulite, also known as gynoid lipodystrophy (Small et al. 2006) is a condition that affects millions of women around the world. Though the presence of cellulite is not a disease, it remains an issue of concern to a great number of women.

Cellulite is the visible fat deposited in pockets under the skin, giving an orange peel effect on the skin in areas around hips, thighs, and buttocks due to excessive development of volume of adipocytes. Collagen fibers that connect the fat to the skin may stretch, break down, or pull tight, allowing the fat cells to bulge out.

Coleus forskohlii extract standardized to 95% forskohlin can be used in skin care as a conditioning and anticellulite agent. Since it is involved in the enzymatic breakdown of fat in the adipocyte cells, it can be useful in the management of cellulite. Forskohlin has shown to potentiate topical fat loss in combination with yohimbine and aminophylline (Bagchi and Preuss 2013).

ForsLean 95% can be used in the form of skin lotion, creams, and patches with a suggested level of 2–5% in the formulation for the management of cellulite.

Clinical results on coleus extract containing forskohlin

In a double-blind study, six women were treated with 25X10E-5 mol/L forskohlin in an aquaphor base on one of the thighs, while the other thigh was treated with base alone. The study was carried out for four weeks with the treatment repeated five days per week. The subjects were also placed on an 800 Cal/day diet and encouraged to walk (Greenway et al. 1995).

After the four-week study period, fat loss under the skin was measured. Results showed that in four women who completed the study, there was significant decrease in the treated thigh girth as compared to the untreated thigh.

Figure 12: Change in thigh girth (Greenway et al. 1995).

Sabinsa also performed a single-centered, randomized, double-blind study to evaluate efficacy of the ForsLean 95% as a novel topical agent for the management of cellulite (Study report: Protocol no. CPL/16/ CELR/ MAR/ 08, 2008).

The study, which was carried out for a duration of four weeks on 54 female subjects with cellulite, showed potential of the ForsLean-containing formulation in reducing cellulite, with a reduction of 9.37% in mid-thigh circumference, and 9.28% reduction in body fat content. In superficial fat reduction, the ForsLean group showed significant difference in all four parameters measured by

ultrasonography. In the anterior-transverse, anteriorlongitudinal, anteriormedial-transverse, and anteriormedial-longitudinal groups, nearly 23.9%, 21.7%, 34.2%, and 34.1% reduction from baseline was observed.

g. Cosmoperine® (*Piper nigrum* fruits)

Cosmoperine® is a patented extract for enhancing topical bioavailability. It is obtained from the hydrogenation of extract obtained from black pepper fruits. The fruits are extracted to obtain an enriched extract containing piperine. This extract is then further hydrogenated under controlled conditions to obtain a 95% tetrahydropiperine containing an off-white-colored extract. Cosmoperine is used in cosmetics for enhancing the penetration of active compounds topically (Ahmed et al. 2012).

Laboratory studies on the Cosmoperine have shown its role in improvement of topical bioavailability of compounds such as betamethasone dipropionate, green tea polyphenols, forskohlin, and other active compounds used in skin care.

Study with betamethasone dipropionate

Bioavailability enhancement effect of Cosmoperine was observed with betamethasone dipropionate in an experiment designed to determine the transdermal diffusion of BMDP through hydrated skin mounted on a Franz diffusion cell. Betamethasone DP is a topical anti-inflammatory ingredient that has a poor absorption potential. It was observed that in the presence of Cosmoperine, the drug completely diffuses through the skin in about five minutes of application. This effect of Cosmoperine can improve the absorption of BMDP, thus making it act faster in the skin and providing the benefits (Sami Labs Report 2000).

Figure 13: Improvement in transdermal absorption of BMDP in presence of Cosmoperine

Study with Green Tea Polyphenols

Cosmoperine® was studied for its bioavailability enhancement activity for three botanical extracts—green tea polyphenols, *Coleus forskohlii* extract, and tetrahydrocurcumin extract (derived from curcuminoids). These three extracts represent different functionalities in cosmeceuticals (antioxidant effect from green tea polyphenols, skin-conditioning effect from *Coleus forskohlii*, and skin-lightening activity from tetrahydrocurcuminoids) and also different solubilities (water-soluble green tea extract and lipid soluble forskohlin and tetrahydrocurcuminoids).

Cosmoperine® enhances the permeation of the green tea polyphenols across the egg membrane by about 30% on average). Cosmoperine® enhanced the permeation of forskohlin by about 40% in the first 30 minutes, when used at the level of 5% of the forskohlin concentration. The antioxidant action of the tetrahydrocurcumin was enhanced by adding Cosmoperine® (Sami Labs Report 2000–2003).

In case of the tetrahydrocurcumin, the free radical scavenging efficacy of tetrahydrocurcumin was evaluated in the absence and presence of Cosmoperine®. The antioxidant activity of tetrahydrocurcuminoids was found to be enhanced by tetrahydropiperine.

Human safety trials with Cosmoperine®

A 48-hour repeat insult patch test was used to evaluate the skin-irritation potential of Cosmoperine®. Cosmoperine® at a level of 0.01% and 0.1% (an effective dose range for the compound), was used in the skin patch test in a petroleum vehicle. The test was conducted on 50 human subjects for 48 hours. Results showed that both the applied dosages were safe and neither dose caused any skin irritation. These results indicate that Cosmoperine® does not act as a skin irritant in a dose range considered effective for topical nutrient delivery (Majeed et al. 2005).

Above study was conducted by US FDA accredited BioScreen Testing Inc Lab.

Clinical Study on Cosmoperine®

Cosmoperine® was evaluated for its topical bioavailability enhancement activity in a combination containing tetrahydrocurcumin formulated for management of photo-aging. The study was performed by Clin World as a three-month prospective, randomized, double-blind, non-crossover, comparative clinical trial with 20 subjects suffering from mild to moderate photo-damaged skin.

While Cosmoperine® by itself does not have any antioxidant properties, its effect on antioxidant activity of THC was evaluated. Antioxidant activity is important for management of photo-aging. The two formulations compared had an equivalent amount of THC (0.5%) while one of them had an additional 0.1% Cosmoperine® for bioavailability enhancement.

The parameters assessed were hyperkeratosis, collagen density, and lymphocyte infiltration.

Hyperkeratosis

The efficacy of creams was evaluated for reduction in hyperkeratosis, and results revealed that the cream X (containing 0.1% Cosmoperine®) was more efficacious in this function.

Figure 14: Comparison of efficacy hyperkeratosis with cream X (containing 0.1% THP and 0.5% THC) with cream Y (containing (0.5% THC).

Collagen Density

Collagen histochemistry has also shown that there was a significant reduction in collagen density with both cream X and Y; however, the comparison of efficacy between the two creams revealed that cream X (containing 0.1% Cosmoperine®) is more effective.

Figure 15: Comparison of collagen density at end of the study

Effect on lymphocyte infiltration

The comparison between the two formulation showed that there was statistically significant reduction in lymphocyte infiltration with both creams X and Y, while there was significant reduction with cream X (containing Cosmoperine® 0.1%) compared to that of cream Y.

Figure 16: Comparison of % efficacy of cream X and Y in lympocytic infiltration

This three-month study showed that tetrahydrocurcumin was effective in reversing the photo-damage to the skin. The comparative efficacy of the cream containing THC (0.5%) and Cosmoperine® (0.1%) was found to be more than the cream containing THC alone. The faster response to the Cosmoperine-containing cream was attributed to the bioavailability enhancing effect of the Cosmoperine® or tetrahydropiperine. The tetrahydropiperine enhances the transdermal bioavailability of the co-administered nutrient or actives. It was concluded from the study that the inclusion of Cosmoperine® in the THC cream was more beneficial in accelerating the reversal of photo-damage on the skin (Sami Labs Report 2006).

The mechanism of Cosmoperine®

Cosmoperine®, which is a lipophyllic compound, may possibly increase the solubilization of the intracellular lipid moiety in the skin, making it more permeable to the applied nutrient or drug.

h. ARTONOX® (*Artocarpus lakoocha* wood)

Artonox® is the brand name for the *Artocarpus lakoocha* extract standardized to 95% of oxyresveratol. *Artocarpus lakoocha* is a large deciduous tree widely distributed in the Southeast Asian region including Thailand, India, Sri Lanka,

Myanmar, Vietnam, etc. *Artocarpus lakoocha Roxb., moraceae* belongs to same genus as jackfruit (*Artocarpus heterophyllus*). This tree is well known for the traditional medicine "Puag haad" (Wongsawad et al. 2005; Palanuvej et al. 2007).

Oxyresveratrol

Figure 17: Structure of oxyresveratrol

Oxyresveratrol (Figure 17), analogous to resveratrol structurally, is a tetraoxygenated stilbene found in mulberry, grapes, red wine, and peanuts. Recently oxyresveratrol has shown activities such as antioxidant, antiviral, anti-inflammatory, neuroprotective, and topically it has been found to have tyrosinase-inhibitory activity (Likhitwitayawuid et al. 2006).

In 2009, research on *Artocarpus lakoocha* extract detected the presence of oxyresveratrol in its heartwood extract, thus providing a new source of this stilbene compound (Maneechai et al. 2009).

Artocarpus lakoocha

Figure 18: Heartwood of *Artocarpus lakoocha*

Recent studies on the *Artocarpus lakoocha* have confirmed the presence of oxyresveratrol in heartwood (Figure 18). Further studies have also revealed the potential use of Artocarpus as a skin-whitening agent (Singhatong et al. 2010).

Development of Artocarpus extract: Artonox®

Scientists working on polyphenols at Sabinsa evaluated the raw material from various species of Artocarpus tree, grown in the Indian subcontinent, such as *Artocarpus heterophyllus*, *A. communis*, *A. chaplasha*, and *A. Lakoocha*. Study showed that *Artocarpus lakoocha* was good a source of oxyresveratrol in its heartwood. Alcoholic extract from the heartwood of Artocarpus was taken up for purification followed by crystallization to obtain a highly enriched Artocarpus extract standardized with oxyresveratrol 95% by HPLC (Figure 19) Artonox®.

Figure 19: Chromatogram of Artonox®

Antioxidant potential for Artonox®

Antioxidant strength of Artonox® was evaluated by both the DPPH and ORAC assay system.

- DPPH Assay

The antioxidant activity of Artonox was initially evaluated by using DPPH radicals. Diphenyl picryl hydrazyl (DPPH) radicals are color stable, free radicals that lose color rapidly in the presence of antioxidants. It is a reliable method for evaluating free radical scavenging activity. Artonox showed remarkable free radical scavenging activity in DPPH assay as compared to other stilbene compounds such as resveratrol, pterostilbene, and kojic acid.

Artonox® (95% oxyresveratrol) exhibited strongest free radical scavenging activity, with IC_{50} of 2.7µg/ml, followed by resveratrol (IC_{50} 3.01µg/ml) and trans-pterostilbene (IC_{50} 4.3 µg/ml). Kojic acid showed the lowest activity, with IC_{50} 500µg/ml (Figure 20) (Sami Labs Research Report—Unpublished).

Figure 20: Antioxidant activity by DPPH assay

- **ORAC activity assay**

Oxygen Radical Absorbance Capacity assay has become a gold standard for antioxidant evaluation. Though primarily used for evaluation of antioxidant capacity of nutritional supplements and foods, today ORAC can be used in the cosmetic field for measuring the antioxidant potential of cosmeceutical ingredients against various free radicals present in the skin environment.

ORAC activity of Artonox was compared with some stilbenes and other antioxidants (Sami Lab Report—Unpublished). Results as shown in Figure 21 below indicate that Artonox® can act as an anti-aging product as well as providing antioxidant cover to the formulation to increase its shelf life.

Figure 21: ORAC activity of selected antioxidants

Skin-lightening potential of Artonox®

The main active compound of Artonox®-oxyresveratrol belongs to family of stilbenoid compounds. Stilbenoid compounds have been reported to possess the tyrosinase-inhibitory activity, with level of oxygenation of stilbene structure clearly affecting the tyrosinase-inhibitory activity. Thus tetra-oxygenated stilbene such as oxyresveratrol displayed ninefold stronger tyrosinase-inhibitory activities than resveratrol, which is a tri-oxygenated stilbene (Likhitwitayawuid et al. 2002).

Skin-lightening activity of Artonox® was evaluated by two methods.

1. Enzyme based tyrosinase-inhibitory assay
2. Cell based melanogenesis-inhibitory assay

1. Tyrosinase-inhibitory assay

The tyrosinase-inhibitory assay is an *in vitro* assay using commercially available mushroom tyrosinase enzyme. It is based on the principle that tyrosinase is a rate-limiting enzyme in melanin biosynthesis and it acts on L-tyrosine to form a pink-colored complex. The progress of the test is measured spectroscopically at 475nm. Skin-lightening agent or tyrosinase inhibitor will inhibit the formation of the complex and thus quench the pink color intensity in the test.

Artonox standardized with 95% oxyresveratrol showed strong tyrosinase-inhibitory activity in the test with IC_{50} of 0.049 µg/ml. This activity was 140 times stronger than kojic acid (Figure 22), confirming the superiority of stilbene compounds over kojic acid for skin-lightening application (Sami Labs Report).

Figure 22: Tyrosinase-inhibitory activity of Artonox and kojic acid

Oxyresveratrol, being a target for the tyrosinase-inhibitory activity, has also been studied for its inhibition mechanism. The studies showed that oxyresveratrol was a noncompetitive inhibitor of mushroom tyrosinase with respect to L-DOPA (Kim et al. 2002).

Sami Labs Report Unpublished.

2. Melanogenesis-inhibitory assay

Studies have shown that some cytokines and growth factors also play an important regulatory role in melanogenesis. α-MSH (melanin-stimulating hormone) is one such factor. It binds to its receptor on melanocytes (cells producing melanin in the skin) and stimulates melanogenesis via cAMP-MITF (microphthalmia-associated transcription factor). Thus agents that block the signal pathway also exhibit the depigmentation against melanocytes (Ding et al. 2011).

Hence the melanogenesis-inhibitory assay was carried out on the Artonox® to estimate its depigmentation activity (Sami Labs Report).

Sami Labs Report Unpublished.

The melanogenesis-inhibitory assay is a cell-based assay where intracellular melanin in B16 F1 mouse melanoma cells is treated with various concentration of sample. The melanin thus formed is later extracted and estimated in a microplate reader.

Artocarpus showed a strong inhibitory activity on melanogenesis with IC_{50} of 12µg/ml as compared to kojic acid, which showed IC_{50} of 100µg/ml.

The melanin is induced by MSH in melanoma cells and treated with varying concentrations of Artonox. The slides below show the dose-dependent inhibition of melanin formation in the presence of Artonox® (Figure 23).

Figure a. MSH-induced melanogenesis in control melanoma cells

Figure b. 32% inhibition of melanin in Artonox-treated cells (10µg/ml)

Fig c. 50% inhibition of melanin in Artonox-treated cells (12µg/ml)

Figure 23: Melanogenesis inhibition by *Artocarpus lakoocha* extract 95%

Anti-inflammatory effect

Artonox® was also evaluated for its anti-inflammatory effects against the carrageen-induced model of inflammation in rats. Artonox significantly reduced the

paw edema. The results suggest that the anti-inflammatory properties of oxyresveratrol may be correlated with inhibition of iNOS expression through down-regulation of NF-KappaB binding activity and significant inhibition of COX-2 activity.

Test	**Artonox® (Oxyresveratrol 95%)**
Elastase inhibition (IC_{50})	120µg/ml
Collagenase inhibition (IC_{50})	92µg/ml

Cosmeceutical application

Artonox® (Oxyresveratrol 95%) acts on some of the major targets that cause undesirable pigmentation, age spots, freckles, and other related skin conditions. Artonox® (oxyresveratrol 95%) has shown good efficacy in various *in vitro* studies conducted by Bio Research Div of Sami Labs Limited. Artonox® (oxyresveratrol 95%) was found to possess significant antioxidant, anti-inflammatory, and skin-lightening potential.

Potential applications can be as:

a. Skin lightening (natural tyrosinase and melanogenesis inhibitor)
b. Anti-aging
c. Antioxidant

i. *Eclipta alba* (Bhringraja)

Eclipta alba is a well-known Ayurvedic herb that has been known for its pharmacological actions including antibacterial, antihepatotoxic, antioxidant, anti-haemorrhagic, and anti-hypeglycemic properties (Pandey et al. 2012). Its use as a hepatoprotectant is quite popular and is a part of many herbal formulations for management of liver diseases.

Eclipta alba grows is widely distributed in the Southeast Asian countries such as India, Thailand, and China. *Eclipta alba*, commonly known as a Bhringraj in Ayurveda, belongs to the family *asteraceae* (Neeraja et al. 2011). A wide range of phytochemicals are present in the *Eclipta alba* including the wedelolactone in the leaves, which is considered as main active in this herb.

Apart from its benefits on oral consumption, it has also been reported to improve hair growth on topical application (Kirtikar and Basu 1975).

Eclipta alba has been evaluated for its potential use in alopecia or hair loss. Alopecia is regarded as a dermatological disorder where the subject suffers from hair loss from the scalp or other parts of the body. It can occur in both sexes and has a lot of psychological implications.

Studies have been performed to look into the possible role of *Eclipta alba* in management of alopecia and hair fall.

In one of the studies (Roy et al. 2008), the researchers evaluated the petroleum ether and ethanolic extract of *Eclipta alba* for their effect on promoting hair growth. The extracts of *Eclipta alba* were incorporated in creams and applied topically on the skin of albino rats. The hair growth was compared with minoxidil 2% solution.

Results showed that the petroleum ether extract showed a greater number of follicles in the anagenic phase of the hair growth, which can be regarded as an active-growth phase of hair follicles, during which the hair root divides rapidly and adds to the hair shaft. The rats in the *Eclipta alba* cream group also showed less time required for the complete hair growth. Overall, the results obtained for the hair growth were better than the positive control minoxidil.

In another study done at Dabur Research Foundation (Dutta et al. 2009), the *Eclipta alba* methanolic extract was evaluated for hair-growth activity in pigmented C57/BL6 mice. These mice were preselected for their characteristic telogen phase of hair growth. The extract was topically applied. The results from the immunohistochemical study performed on the mice showed that *Eclipta alba* was able to induce the anagen phase in the mice. The study showed that *Eclipta alba* can be used as a hair-growth promoter.

Sabinsa manufactures the *Eclipta alba* extract with 50% wedelolactone, which is the active component in the leaves of the plant. This extract can be used for formulation of hair care products.

Figure 24: Structure of ursolic acid

j. Ursolic acid (*Salvia officinalis* leaves)

Ursolic acid occurs in nature in several edible fruits such as apples, basil, cranberries, peppermint, and rosemary. Chemically, ursolic acid is a pentacyclic triterpenoid acid, whose anti-inflammatory activity and its activity in inhibiting various types of cancer have been well studied. Studies have shown that it may inhibit the proliferation of cancer cells and also induce apoptosis (Shishodia et al. 2003; Wang et al. 2011).

It is found often along with another triterpenoid—oleanolic acid, which is structurally very similar to ursolic acid.

Anti-inflammatory activity is found in several triterpenoid, and ursolic acid is no exception. Ursolic acid has shown anti-inflammatory activity against mouse ear edema caused by 12-o-tetradecanoylphorbol-13-acetate. The mechanism of the anti-inflammatory activity has been suggested to be through histamine release from mast cells, reducing production of arachidonic acid by inhibiting enzymes such as cycloxygenase and lipoxygenase. Inhibition of inflammatory enzymes such as elastase was also thought to play a role in the anti-inflammatory activity of ursolic acid (Liu 1997).

Apart from the anti-inflammatory activity of ursolic acid, which can play an important role in the anti-aging formulations, ursolic acid has also been found to increase the ceramides and collagen in the skin. In a published study, a liposomal preparation of ursolic acid was found to increase ceramide content of cultured human keratinocytes as well as increase in collagen content of cultured human dermal fibroblast cells. The research also claims that the said liposomal preparation also increased the ceramide content in human skin over an 11-day period (Yarosh and Brown, 2000).

In 2003, Nishimori et al. found that ursolic acid on topical application shows marked improvement of collagen bundle structure and shows reduction in wrinkling without any side effects. The degenerative changes in collagen bundle structure can cause the skin wrinkles and loss of elasticity in the skin.

Use of ursolic acid in cosmeceuticals

Extracts containing ursolic acid can be used in the anti-aging formulation for the repair and anti-wrinkling effect on skin. The suggested level of the use is 1–5%.

k. Boswellin® CG (*Boswellia* extract)

Boswellia serrata is also known as Indian frankincense or salai. Boswellia finds description in Ayurvedic literature for its application as an anti-arthritic supplement. Boswellia has been used since ancient times in many civilization for preparation for incense, medicine, cosmetics, and perfume.

Boswellia extract is obtained from the gum resin of the Boswellia tree. The gum resin is collected from the tree by scraping away the bark of the tree and collecting the exudates from the tree.

The gum resin thus obtained is known for several pharmacological activities, such as anti-diabetic and anti-rheumatic; it is also used for treatment for diarrhea, neurological disorders, mouth sores, and hepatic stimulant.

In Ayurveda, Boswellia has been used for the management of several inflammatory conditions both internally as well as topically. The anti-inflammatory properties of Boswellia can be attributed to the presence of Boswellic acids (Majeed et al. 1996). Boswellic acids are unique, as they inhibit both 5-lipoxygenase and human leukocyte elastase enzymes (Safayhi et al. 1997). 5-lipoxygenase enzyme catalyzes the conversion of arachidonic acid into inflammatory molecules such as leukotrienes.

Anti-inflammatory activity of boswellic acids is one of the most sought-after pharmacological properties—and is also responsible for its cosmeceutical applications.

Anti-inflammatory activity of boswellic acid is directed towards two inflammatory enzymes.

1. Lipoxygenase enzyme
2. Human leukocyte elastase enzyme

Human leukocyte elastase is a serine protease enzyme that initiates injury to the tissue. This injury then triggers the inflammatory process. The tissue injury thus releases the HLE enzyme, which then starts digesting or breaking down the elastin and collagen type IV in the skin, causing the loss of elasticity and texture.

Boswellic acids present in the Boswellin® CG can help to reduce the inflammatory enzymes present in the skin and thus can reduce or slow down the aging process. The dual inhibition of 5-lipoxygenase and human leukocyte elastase is unique to boswellic acids.

Sabinsa performed a clinical study (Mainkar et al. 2003) on Boswellin® CG to determine its application in reducing the puffiness and dark eye circles. Twenty-one female subjects aged 21–35 years were selected for the study.

The subjects were divided into two groups; one group was provided with "Under Eye Cream" containing 1% Boswellin® and the other was given placebo cream. The cream was applied under each eye twice a day for period of four weeks.

At the end of the study the dark circles and puffiness were assessed by a dermatologist.

The results showed that there was 42% reduction in the dark eye circles at two weeks and at the end of the study there was 86% reduction in the dark eye circles. Boswellin CG was found to be safe and effective in reducing the dark eye circles (Figure 25).

Figure 25. Efficacy of under-eye cream vs. placebo treatment

Boswellin® CG has been clinically evaluated as a topical agent in analgesic formulation (Figure 25) (Research Report Sami Labs February 2000).

In an open field study, a topical cream Chilisin® consisting of boswellic acids, capsaicin, and methyl salicylate was evaluated in 12 volunteers monitored by several independently working chiropractors. This study was coordinated by Synergy Wellness Clinics, DeSoto, Texas.

The study showed that Chilisin® cream applied regularly on a daily basis for atleast two weeks resulted in significant improvement in all parameters tested, with pain score diminished by half as a result of treatment with Chilisin®.

Figure 26: Mean scores of arthritic symptoms as evaluated in an open field study of boswellic acids containing topical analgesic Chilisin®.

4.1.5.6 SUSTAINABILITY OF BOTANICALS

Today the demand for the herbal and natural actives in the market is growing at a tremendous pace, which requires careful planning towards growing, harvesting, and procuring the raw material. The natural resources are limited and increasing

consumer demand puts pressure on the natural resources. To meet these demands, proper utilization of the natural resources is a must. Crop rotation, replantation, and improved high-yield variety can be useful tools in creating the sustainable natural resources.

CONCLUSION

In this chapter we have described the various multifunctional natural/nature- derived extracts for skin and hair care. Plant-derived ingredients are gaining increasing acceptance both from the formulators and consumers. Green products are safe and are more skin friendly, and their use results in fewer chemicals and toxins being released into the environment. Use of such ingredients is an imperative in today's world since we have now embraced the concept that the use of natural resources must be carried out responsibly, and in eco-friendly manner.

INGREDIENTS TO STRENGTHEN SKIN BARRIER INTEGRITY: From Algal Protective Exoskeleton to a Protective Barrier for the Epidermis

Author

Alexandra Jeanneau
Scientific communication officer,
Alban Muller Group

ABSTRACT

The skin epidermis serves numerous functions, but its primary purpose is to act as a protective barrier for the body from the external environment. It is composed of keratinocytes piled in layers lying upon each other thanks to specific complex junctions maintaining cohesion and communication among them. With aging this "young" architecture becomes disorganized, and this leads to a weaker protection and poorer communication of information signals between cells.

Some living organisms have developed a protective mechanism to this disorganization by an adaptation to their environment. For instance, *Padina pavonica*, a brown alga, builds an organized external deposit of calcium carbonate in the form of aragonite crystals for its protection.

As calcium bioavailability is necessary for the synthesis of essential epidermis structures, a high-tech active extract of *Padina pavonica* was developed and studied. This study highlights the activity of the extract for maintaining bioavailable calcium and thereby stimulating the synthesis of calcium-depending structures, crucial for the epidermis-protective function.

INTRODUCTION

The primary function of the epidermis is to act as a protective barrier for our body from the external environment. Maintaining its integrity and resistance is crucial for proper functioning of the skin. In view of this function, and our present understanding of it, there is considerable ongoing research on skin to improve its strength and to find new active ingredients with innovative modes of action that improve its integrity.

4.1.6.1 SKIN BARRIER AND EPIDERMIS ORGANIZATION OVERVIEW

Skin barrier function resides primarily within the *stratum corneum* (SC), the top layer of the epidermis. It plays a vital role in forming a protective barrier and helps to prevent percutaneous entry of harmful pathogens in the body.

Epidermis is the upper layer of the skin tissue, just below the *stratum corneum*. It is composed of several layers of keratinocytes that undergo continuous

morphological changes reflecting their underlying keratinization as a protective barrier of the epidermis (both mechanical and chemical).

This epidermal differentiation begins from the depth to the surface of the epidermis cells and enables the distinguishing of four layers on a skin cut: the germinal layer (or basal), the spiny layer (or spinous), the granular layer and horny layer, or *stratum corneum* (first compacted then desquamating). Each stage of epidermal differentiation is characterized by the expression of specific proteins.

Therefore, maintaining a good level of proliferation and differentiation of keratinocytes from within the epidermis is crucial for the proper functioning of the skin barrier and for its integrity. Thus, the most important function of keratinocyte differentiation is the establishment and maintenance of the *stratum corneum*, since the latter consists of corneocytes and extracellular lipids secreted by differentiated keratinocytes, which together function as a barrier against the entry of chemicals and microbes from the environment and protect the body from dehydration (Figure 1).

Figure 1

a. Epidermal cells structures for skin resistance and cohesion

The mechanical strength of the epidermis depends on the integrity of the epidermal cell skeleton, which primarily consists of cytokeratins. Keratinocytes are piled in layers of cells, lying on each other, in which cytokeratins are synthesized in high quantities. Cytokeratins are specific proteins building the cytoskeleton of keratinocytes and responsible for their resistance. In each layer, daughter cells only differ from mother cells by the maturation of cytokeratins, which undergo modifications from the deepest layer of the epidermis to its surface. The most external layers are made of corneocytes (final form of the keratinocytes' differentiation) that no longer contain a nucleus and are filled with almost only a framework of modified cytokeratins.

The structural integrity of the skin also depends on dynamic junctions between cells called desmosomes. They are special membrane-associated structures of the epidermis equivalent to press studs that attach or detach depending on the cell needs. Indeed, the formation of desmosomes mostly takes place in the basal layer, the deepest one in the epidermis, where it is favored by the palissadic arrangement in perpendicular layers of keratinocytes placed very near one to the other. Having a particular structure at the junction of the basal layer with the dermis, where they are called hemi-desmosomes, desmosomes evolve from one layer to the other to end up in corneo-desmosomes at the *stratum corneum* level, where enzymes break them to favour the desquamation process.

Desmosomes are highly organized and build an intercellular adhesion point strongly anchored by cytokeratin filaments that penetrate deeply into the cytoskeleton, thus ensuring cohesion for the functioning of the epidermis.

The resulting "clipped" architecture of the epidermis explains its resistance and cohesion but also favors good intercellular signals, which are necessary for its proper function (Figure 2).

Figure 2

b. Cell structures depending on calcium

Indeed, desmosomes and cytokeratins are closely associated with each other, ensuring the junctions between keratinocytes and the cohesion between epidermis and the underlying dermis. It is therefore important to emphasize the critical role of both structures for the consolidation of the mechanical function and the integrity of the epidermis.

Cell communication is ensured by chemical messengers passed from one cell to another, a process that also depends on desmosomes and cytokeratins cell structures, which are calcium-dependent.

Indeed, calcium is involved in the maturation of cytokeratins as well as in the adhesion of the desmosomial proteins. Calcium ions are transferred from the blood to the most superficial cells by channels specialized in ionic transport in cell membranes. Calcium is then attracted to the structures on which it must act, particularly cytokeratins and desmosomial proteins.

c. Calcium's information-signaling properties

Calcium is an excellent information aid, as it can combine with a number of acids and be included in many minerals. The same salt with the same chemical formula can result in different minerals, depending on the atomic arrangement. Indeed, oyster shell, for instance, is covered by an outer layer, the thickest one, made out of an amorphous (thus nonorganized kind of calcium carbonate) and a thinner layer of shining calcite, itself covered with mother-of-pearl; the two latter minerals are crystallized (thus organized) forms of calcium carbonate. The soluble form of these minerals releases calcium ions with distinct solubility coefficients in the surrounding media and are able to pass on electric potentials at different levels. This process allows for the circulation of information. In mammals, the role of calcium is essential for blood coagulation, muscle contraction, nervous influx transmission, and heart rhythm regulation.

Signaling information associated with calcium in the skin is observed at two levels: the maturation of cytokeratin proteins that set up mechanisms of apoptosis, program cells' death for protection purposes (renewal of the epidermis), and the organization of skin's immune defense. Indeed, the terminal differentiation of epidermal keratinocytes, linked to the maturation of cytokeratins, is an essential process for the renewal of keratinocytes and ends in the formation of enucleated "dead" cells: the corneocytes. Therefore, *calcium is a key regulator in epidermis homeostasis of keratinocyte proliferation and differentiation.*

Many studies highlight the signaling function of calcium ions on keratinocytes as promoting cell-cell adhesion, and differentiation-related genes. Some studies (1–2) provide evidence that keratinocytes deficient in the calcium-sensing receptor fail to respond to calcium stimulation and to differentiate, indicating a role for the calcium-sensing receptor in transducing the Ca^{2+} signal during differentiation. It has also been observed that calcium is involved in recovery and wound-healing. Immediately after a scratch, there is a wave of increased calcium ionic transport outward from the damaged area that remains elevated in a peripheral layer of cells around the damaged area for several minutes and then disappears gradually. These studies confirm a signaling pathway that appropriately directs the wound-healing process in epidermis (3). Calcium signaling via gap junctions might be involved in the induction of calcium waves in response to mechanical stress at the upper layer of the epidermis (4).

4.1.6.2 SOLUTION FOR ALTERATIONS IN EPIDERMIS

Skin aging is characterized by a variety of morphological and physiological alterations of the epidermis including a lesser communication between keratinocytes, a flattening of the dermal-epidermal junction, a loss of cell cohesion, and a slow-down of the cells' turnover rate that leads to subsequent slowing of the wound-healing process.

a. Epidermis structures responsible for epidermis resistance

Studies on skin aging highlight targeted action on key epidermis structures involved in skin barrier strength, cohesion, and integrity. Such epidermis structures are tight-junctions, dermal-epidermal junction, epidermal growth factor, etc.

Tight junction (TJ) is recognized as a second barrier of the skin. Evidence from some studies suggests that altered expression of (TJ) proteins leads to an abnormal permeability barrier and that the TJ could be affected by the status of the *stratum corneum* barrier. Moreover, there is increasing evidence now that TJ in skin, which localizes in *stratum granulosum*, also contributes to epidermal barrier formation. Among TJ proteins, claudin-1 and claudin-4 have been demonstrated to have a role in barrier function of the skin (5). Other studies on specific cell-adhesion proteins (such as beta-catenin, which provides stability to epithelia under stress) suggest that beta-catenin helps to fortify *adherens* junctions under mechanical stress, which in turn leads to the strengthening of tight junctions (6).

Aging leads to changes in the dermal-epidermal junction (DEJ), including a decreased thickness of the junctions and a reduction of the cytoplasmatic cell strands consisting of basement keratinocytes in the epidermis. DEJ is a complex anchoring structure that connects epidermis and dermis layers together. The epidermis basal keratinocytes are attached to the DEJ basement membrane through hemi-desmosomes. This basement membrane consists of the lamina densa and the lamina lucida. The latter is the area where the molecules associated with adhesion (e.g., integrins, laminin 5, fibronectin) are found. These allow for the binding of epidermal cells to each other. Collagen IV is the most important component of the DEJ lamina densa and acts as a basic support for the other components such as laminins, which represent, as such, the most important component of the basement membrane after collagen IV.

The result of a reduction in the surface of the DEJ (unfolding) leads to a reduction of resistance of the tissue, a reduction in skin firmness, an increase in the formation of wrinkles, and a stretched appearance of epidermis less resistant (7). All of these phenomena are, of course, "symptoms" of aging.

- Filaggrin is involved in epidermal differentiation and skin barrier formation. It specifically interacts with intermediate filaments, particularly keratins. Filaggrin binds to keratin intermediate filaments, causing their aggregation into macrofibrils which are aligned in tightly packed parallel

arrays. This process contributes to cellular compaction and permits extensive cross-linking of keratin intermediate filaments to form a highly insoluble keratin matrix. This matrix acts as a protein scaffold for the attachment of cornified envelope proteins and lipids that together form the *stratum corneum*. Filaggrin protein normally assists in cytoskeletal aggregation and formation of the cornified cell envelope, providing additional strength and structure. It is required for normal lamellar body formation and content secretion. Therefore, it has been highlighted that a fillagrin mutation contributes to a disrupted epidermal barrier, increased water loss, and inflammation (8).

b. Improving calcium bioavailability

Another solution to reinforce skin barrier integrity is to improve the skin's natural function and to enhance calcium bioavailability.

Epidermis (human exoskeleton) contains a high quantity of calcium (a hundred times more than in the dermis), which is involved in cell proliferation and differentiation. With aging, disruptions of mechanisms involved in the calcium metabolism (transport and fixation) appear, and a noticeable decrease of its mobilization results. This process leads to a decrease in the bioavailability of calcium, which in turn disturbs the epidermis homeostasis. This occurs in spite of the fact that its level in the blood remains remarkably stable. *The aging process is thus connected with a significant loss of the bioavailable calcium in the organism* (Figure 3).

Figure 3: level of calcium fixed in the keratinocytes is proportional to the quantity of HFP added in the culture medium

The direct consequences of the process above is a poorer communication between cells, and a lessened resistance of the epidermis. Indeed, the quantity of cytokeratins in the epidermis decreases as general protein synthesis slows down and degradation enzymes are activated.

The degradation described leads to a weaker maturation wave in the epidermis. Keratinocytes lose their perfect organization and cell connections are less effective as they are not in an optimal environment. They are no longer synchronous and communicate poorly. The epidermis cohesion is disrupted. This phenomenon follows the upward migration of the keratinocytes and is visible within the whole thickness of the epidermis, up to the *stratum corneum* which presents a more or less disrupted aspect. As a result, the skin surface becomes rather rough and fluffy (Figure 4).

Figure 4

Improving calcium bioavailability in the epidermis is therefore a key factor for proper functioning of the keratinocytes. This is possible, especially since a stable pool of calcium is available in the vascular environment of the skin and the blood.

4.1.6.3 A NATURAL INGREDIENT TO STRENGTHEN SKIN BARRIER INTEGRITY INSPIRED BY ALGAE PRIMITIVE BEHAVIOR

A knowledge of nature is a pool of information that has inspired the cosmetic industry to find natural solutions to improve the human skin physiological mechanisms. For instance, the unique strategy of adaptation of the *Padina pavonica* alga to its environment is a source of inspiration for the development of effective skin care ingredients.

a. A primitive strategy involving calcium

Padina pavonica, a brown alga belonging to the *Dictyotaceae* family, has developed a set of mechanisms to preserve its vegetative structure to its environment, thereby allowing it to survive in most extreme conditions encountered in the Atlantic Ocean and Mediterranean Sea. This alga builds on the surface of its thallus an organized fan-shaped deposit of calcium carbonate in the form of aragonite crystals (Figure 5a and 5b).

Figure 5a

Figure 5b

The formation of this exoskeleton needs messenger molecules to be sent from the deepest cells of the alga to its surface to initiate the crystallization of aragonite, as this does not occur naturally in seawater. Indeed, this aragonite bio-crystal cannot be formed spontaneously in seawater. It is usually formed under the influence of biological agents, under considerable and very precise conditions of temperature and pressure.

b. An ingredient with a unique mode of action

Knowing the crucial role of calcium in epidermis structures and skin resistance led to an interest for the development of a *Padina pavonica* extract able to mobilize calcium metabolism by human keratinocytes.

Underwater farms and a manufacturing unit have been set up in Malta for reasons related to the culture of the alga itself that grows nearly all the year round in the southern Mediterranean.

A technique for the extraction of the active fraction of *Padina* was developed to produce extract of *Padina pavonica*: HFP (hydrophilic fraction of *Padina*). The

result of the manufacturing process is a hydrophilic fraction of this alga prepared in a glycerin- and preservative-free carrier. After having extracted the active molecules, expected to be messengers synthesized by *Padina*, tests were carried out on human keratinocytes and skin explants.

Efficacy tests highlight an action on the skin by improving cell communication and optimizing cytokeratins and desmosomial proteins synthesis strongly implicated in the cohesion and strength of the skin structures. Moreover, in the presence of pollutants (acid industrial, smoke, tobacco, exhaust gas, . . .) HFP helps the skin to fight against destructuring agents and thus prevents premature aging of the skin.

These results lead to a conclusion that HFP contains water-soluble messenger molecules responsible for the crystallization of aragonite on the padina's surface. The active extract is thus able to act on the calcium-depending cell structures of the epidermis: it actively mobilizes calcium, generating a considerable increase in the synthesis of desmosome and cytokeratins. Thanks to the neo-formation of desmosomes and cytokeratins, the intercellular communication is restored at a good level of efficacy. *The improvement of calcium metabolism restores integrity in the epidermis and helps keratinocytes to recover all their functionalities.*

Skin was found to recover its original "young" cohesion properties responsible for its mechanical and biological resistance. This, of course, makes it the most important protective organ of the organism. As a result, skin looks firmer and younger. Even under the stress of environmental pollution, the HFP protects the skin and maintains a good level of epidermis structures.

c. Stimulation of calcium-depending cell structures

1. Cytokeratin synthesis

Cytokeratins belong to the intermediary filaments family and build up not only the framework of the epithelial cells but also pass on the transduction of signals from the environment to the cell nucleus. This is why their role is so important for the cellular cohesion and communication. A decrease in the synthesis of these proteins is observed with aging and is amplified in the presence of pollutants.

A test was carried out on human keratinocytes HaCaT put into wells and incubated in a culture medium at 37°C during a single night. Cultures were then rinsed with a sterile buffered solution and treated with 50µg/ml HFP.

The dosage of cytokeratins was made by means of the ELISA immune-enzymatic technique, which is based on the fixation of an antibody specific to the synthesized cytokeratins. The complex formed is revealed with a second antibody in solution, combined with an enzyme that reacts with a last substrate. The absorbance of the solution is measured at the specific wavelength of the final complex. It is proportional to the quantity of cytokeratins that is expressed in ng/ml.

(Figure 6) This assay shows a sizeable stimulation of the cytokeratins synthesis in presence of Hydrophilic Fraction of Padina: about 85% versus the control.

Figure 6: Stimulation of cytokeratin synthesis by HFP

Non –treated Keratinocytes (control) Keratinocytes treated with HFP (20µg/ml)

2. Desmosome formation

Desmosomes are disk-shaped junction structures that allow keratinocytes to adhere one to another and resist mechanical tractions: they ensure the epidermis's resistance. With age, their number lessens, which is one factor of the skin aging process.

A test is carried out on human keratinocytes HaCaT treated with increasing concentrations of HFP, incubated for 72 hours at 37°C, and rinsed. Cells are then fixed and kept at 4°C. Desmosomial proteins are made visual with the indirect immunofluorescence technique (SIGMA).

(Figure 7) The fluorescence intensity depends on the concentration in HFP. This means that the expression of desmosomes is HFP dose-dependent.

Keratinocytes treated with HFP (50µg/ml) Keratinocytes treated with HFP (100µg/ml)

Figure 7: Stimulation of the expression of desmosomial proteins by human keratinocytes under the effect of HFP

d. Restoring intercellular communication, a key factor of the epidermis's functioning

As in every organ, cell communication is an essential functioning mechanism. It allows all cells to get information about any occurrence that could disturb the organism's balance and to react properly and quickly. With age, this information network loses its efficiency and the skin defense process decreases.

A fluorescent marker, Lucifer Yellow (LY), is used. It does not spontaneously penetrate into cells but can diffuse from one to another through specific communication junctions (gap junctions) by migrating in intercellular spaces.

A test is carried out on keratinocytes previously grown to confluence, both in the culture medium control and in the culture medium containing HFP. After one night of incubation at 37°C, cell cultures are cut in their middle and the solution of LY is added. After incubation, they are fixed and observed with a fluorescence microscope (Figure 8).

Control culture with LY Culture impregnated with LY and treated with HFP (50µg/ml)

Figure 8: cell communication restored between keratinocytes

HFP favours cell communication by improving the transfer of messengers from one cell to another. Calcium-signaling via gap junctions might be involved in the induction of calcium waves in response to mechanical stress at the upper layer of the epidermis (4).

e. Improving skin barrier integrity: a better protective shield against pollution

HFP active cosmetic ingredient is able to restore the epidermis structure, even in aggressive conditions. Despite the presence of destructurating agents, tests carried out on skin explants highlight induction of the expression of the cell element involved in the solidity and cohesion of the epidermis.

The destructurating agents used for the tests were sulfuric acid and nicotine. Sulfuric acid is a polluting agent contained, for instance, in exhaust gas and industrial smoke. A number of scientists connect it to the premature aging of the skin in cities. Nicotine is a component of tobacco pollution. It would have a deleterious effect on the skin by activating enzymes responsible for the degradation of the intercellular cement and by damaging the junction structures of keratinocytes.

Tests were carried out on skin explants from plastic surgery implemented on a 51-year-old woman. The control explant is immediately deep-frozen at –70°C. The other explants are placed in a culture medium, the epidermis upwards, and incubated for eight days while treated every two days with the creams to be tested. They are then deep-frozen at –0°C, cut into 5µm fine pieces with a cryostat and stored at –70°C until histological staining and immune-marking procedures are made.

Skin explants were treated with a cream containing 1% of a destructurating agent (sulfuric acid or nicotine) alone or with 4% of HFP in a cream. Desmosomial and cytokeratin proteins were made visual on skin sections by the indirect immunofluorescence technique.

The test carried out proves that HFP alleviates the deleterious effects of sulfuric acid and nicotine. It helps the skin to keep a normal metabolism.

(Figure 9) The intensity of fluorescence expresses a higher synthesis of desmosomes in the presence of HFP.

Skin at D0 (Control) Cream with 1% nicotine D8 Cream with 1% nicotine + 4% HFP D8

Figure 9: Expression of desmosomial proteins in presence of nicotine

(Figure 10) In the presence of a powerful pollutant such as sulfuric acid, the fluorescence is only observed in the deepest layers of the epidermis. On the contrary, when the skin explants are treated with the cream containing HFP, the fluorescence is more intense and distributed in the whole thickness of the epidermis.

Skin at D0 (Control) Cream with 1% sulphuric acid D8 Cream with 1% sulphuric acid + 4% HFP D8

Figure 10: Expression of cytokeratins in presence of sulphuric acid

This proves that HFP protects the structure but also the organization of the major cytoskeleton components in all cell layers of the epidermis.

Observations of histomorphological skin sections treated with 1% nicotine show that HFP protects epidermis in an aggressive environment (Figure 11).

Skin at D0 (Control) Cream with 1 % nicotine – D8 Cream with 1 % nicotine and 4 % HFP - D8

Figure 11: histomorphological views of skin sections

Epidermis of skin explants treated with the cream containing only nicotine is considerably thinner compared to the control, and presents only two to three cell layers. When the explants are treated with the cream containing HFP, the structure of the epidermis doubles versus nicotine only.

CONCLUSION

Nature offers a wide variety of potential solutions for customers' needs provided by the cosmetic industry. This study highlights the benefits of the active hydrophilic

fraction *Padina pavonica* alga to restore skin ability and its metabolism to maintain and reinforce its integrity via calcium-depending structures. It is a new ingredient to strengthen skin barrier with a unique mode of action targeted and highlighted with efficacy tests. Some other studies, described elsewhere (9), discovered the power of this alga to act also on the fixation of calcium within the extracellular matrix of osteoblasts, giving another potential opportunity against osteoporosis.

GLOSSARY

- **Dermal-Epidermal-Junction (DEJ):** also named cutaneous basement membrane. It is an acellular zone that is between the dermis and the epidermis. It binds tightly the epidermis to the dermis. It determines the polarity of the basal keratinocytes, the spatial keratinocyte organization and the epidermal architecture; the epidermal stratification proceeds with the proliferating keratinocytes remaining attached to the basement membrane and the daughter cells migrating into the upper layers. It serves as a selective barrier allowing the control of molecular and cellular exchanges between the two compartments. It has also a fundamental role during the wound re-epidermization, by serving through its constitutive glycoproteins (mainly laminins) as a substrate for adhesion and migration of keratinocytes.
- **Fibronectin:** a glycoprotein of the extracellular matrix that binds to membrane-spanning receptor proteins called integrins. Similar to integrins, fibronectin binds extracellular matrix components such as collagen, fibrin, and heparan sulfate proteoglycans
- **Integrin:** a large family of homologous transmembrane, cell-matrix adhesion receptors mediating the attachment between a cell and its surroundings, such as other cells or the extracellular matrix (ECM). It transmits information about the chemical composition and mechanical status of the ECM into the cell. Therefore, in addition to transmitting mechanical forces across otherwise vulnerable membranes; they are involved in cell signaling and the regulation of cell cycle, shape, and motility.
- **Lamina lucida:** a component of the basement membrane. It is 20 to 40 nm thick and is traversed by anchoring filaments rich in laminin-5 and laminin-6 and which interact with the extracellular domain of α6 β4 integrin at the cell surface of keratinocyte to form an adhesion structure with the hemi-desmodomes.
- **Lamina densa:** a component of the basement membrane below the lamina lucida. It has a thickness that varies with age from 30 to 60 nm and is mainly composed of type IV collagen but contains also laminin-10

and laminin 7, nidogen, and heparan sulfate proteoglycans, a major one being perlecan. It constitutes the intermediate anchorage zone for the anchoring filaments originating from the epidermis and the anchoring fibrils issued from the fibrillar zone of the dermis.

- **Laminin 5:** major component of *lamina lucida* and one of the key components of the anchoring complex.
- **Thallus:** vegetative system (body) of algae and fungi.
- **Tight-Junction (TJ):** multiprotein complexes that mediate cell-cell adhesion and regulate transportation through the extracellular matrix. Because tight junctions encircle the cell and attach it tightly to its neighbors, these junctions act as a barrier preventing molecules from diffusing across an epithelial sheet between adjacent cells.

ANTIMICROBIAL PRESERVATIVES FOR THE COSMETIC AND PERSONAL CARE INDUSTRY

Author

Daryl Paulson Ph.D.
President and Chief Executive Officer
BioScience Laboratories, Inc.

ABSTRACT

Most of the cosmetic and personal care products and ingredients our industry produces are subject to degradation. This occurs from a variety of sources such as contamination from microorganisms – bacteria and fungi – or, from a chemical perspective, UV light, oxygen reduction, heating and cooling (1). **We know, then, that substances degrade, but can the length of time prior to product degradation be extended to make it acceptable in the market?** This is the heart of the matter of this chapter. It is essential reading for individuals involved in the technology, marketing and business aspects of producing new products which will be re-purchased by consumers- for no matter how good the product is, no matter what the breakthrough and claims are, if the product degrades to something different than when it was made, it simply wont work anymore and no one will buy it.

4.1.7.11 THE USE OF PRESERVATIVES IN COSMETICS, A BRIEF HISTORY

The Food and Drug Administration, established in 1931, enforced the Food and Drug Law of 1906, which was revised in 1938 to become the Food, Drug and Cosmetic Act, officially adding cosmetics. Research on preservatives began, in response to microbiological problems, specifically visible mold growth on cosmetics. At this time, parabens became well known for their antifungal activity and became the preservative of choice.

Microbiologists of the 1950s conducted efficacy studies on the biocides to determine their spectrum of activity.

However, antibacterial compounds do not necessarily convey preservative properties. Even the annual FDA list of antibacterials used in products does not differentiate between actives and preservatives. Antimicrobials that are active ingredients primarily kill gram-positive flora on body surfaces. Antimicrobials that are preservatives primarily kill molds, yeasts, and gram-negative flora in products. Despite a product containing a biocide, one should never expect the antibacterial active to also act as a preservative or vice-versa.

Our first focus in this chapter is preventing spoilage by microbial contamination. It should be recognized that bacterial growth might be occurring, but the product does not show this visibly. However, if the product is used, it may cause an infection to normal skin surfaces, or it may even invade skin areas that have been damaged, cut, or broken and cause an infection. Notice that, while microorganisms are ubiquitous to our surroundings in the normal environment, when they get into a product that has the nutrients they require, they can grow in rather large quantities.

If this happens to one of your products, then all of the marketing, advertising, and promotion will be useless, as people stop purchasing your product. If an infection occurs, you can face a large legal claim.

What is also needed are effective preservatives that greatly slow the degradation of a product and do not compromise the product's effectiveness.

4.1.7.12 TRADITIONAL PRESERVATIVES

Preservatives

The first area to discuss is the microorganisms—bacteria and fungi; they require certain minerals, sugars, and lipids in order to grow. Many can get them from products. To grow successfully, microorganisms require suitable temperatures, pH levels, and water activity, and the growth medium must be free from ionizing radiation (Hansen & Shaffer 2001). Most products we will be discussing contain these.

These microorganisms are widely distributed in nature and are able to utilize a wide range of materials as sustenance for growth. Most contamination is a combination of bacterial and fungal species, combined (Fassihi 2001). For example, a fungi may break the compound into the substances that it needs to live, creating by-products that are suitable for bacterial growth. Microbial growth, however, is not the only thing that preservatives are used to prevent. The ingredients of many products are not in a stable condition. As time passes, the product goes into a more unstable condition, until finally, the product no longer works as expected. The fungi can also produce extracts (e.g., penicillin) that will inhibit the growth of bacteria but allow the specific fungus to grow (Moore & Jaciow 1979; Ryan 2010).

The importance of choosing the proper preservative is important. Suppose one is making a hair shampoo to be sold in the USA. The product was a huge hit, and the manufacturer decided to expand the markets to include Japan and Canada. Unknown to her or her team was that both these countries have different views of the product, and the preservative could not be sold in these countries.

This is an obvious simplification, but this is the way various countries react. So, both the ingredients and the preservatives must be assured to be satisfactory in other countries if the product is to be sold in them.

Let me give the preservative and its frequency of use in the U.S. and Canada for 2010 (Steinberg 2012).

INCI Name	U.S. 2012	Canada 2010
Methylparaben	13434	54668
Propylparaben	10421	34075
Phenoxyethanol	8878	34075
Butylparaben	5289	20451
Ethylparaben	4869	18511
Isobutylparaben	2693	10542
Methylisothiazolinone	2408	9068
Methylchloroisothaizolinone/ Methyliosthiazolinone	2235	8445
DMDM Hydantoin	2035	7434
Imidazolidinyl Urea	2007	7998
Benzyl Alcohol	1991	6344
Caprylyl Glycol	1712	4466
Diazolidinyl Urea	1644	9212
Sorbic Acid/Potassium Sorbate	1037/1456	3224/6257
Benzoic Acid/Sodium Benzoate	604/1334	1788/5123

INCI Name	U.S. 2012	Canada 2010
Chlorphenesin	1065	3493
Dehydroacetic Acid/Sodium Dehydroacetate	948	1531/3470
lodopropynyl Butylcarbamate	834	3373
Ethylhexylglycerin	712	2580
Penetylene Glycol	705	1882
Triclosan	494	1589
Sodium Methylparaben	465	1754
Quaternium-15	389	1156
Isopropylparaben	336	1745
Chlorhexidine Dihydrochloride	224	293
Chlorhexidene Digluconate	195	832
1,2 Hexandiol	162	383
2-Bromo-2-Nitro-1,3-Diol	158	1320
Sodium Propylparaben	139	379
Citrus Grandis (Grapefruit) Seed Extract	108	755
Benzalkonium Chloride	97	260
Polaminopropyl Biguanide	96	254
Methyldibromo Glutaronitrile Sodium	93	1036
Hydroxymethylglycinate	90	1050
o-Cymen-5-ol	84	302
Phenethyl Alcohol	63	343
Lactoperoxidase	61	305
Chloroxylenol	58	282
Formic Acid and its salts	48	122
Hexamidine Isethionate	45	1
Phenxyisopropanol	29	35
Benzethonium Chloride	26	163
Triclocarban	26	48
5-Bromo-5-Nitro-1,3-Dioxane	23	74
Piroctone Olamine	20	124
Dichlorobenzyl Alcohol	15	49
Climbazole	13	23
Hinokitol	11	61
Polymethoxy Bicyclic Oxazolidine	10	165
Chlorhexidine Acetate	9	0

INCI Name	U.S. 2012	Canada 2010
Glutaral	9	21
Quaternium-73	8	32
Methenamine	6	36
Thimersal	6	0
Silver Chloride	5	12

Each of these preservatives acts in ways that prevent bacteria and fungi from growing and causing degradation of the final product. The reason why there are so many preservatives is there are vastly different chemistries in product formulations, and the preservatives cannot break down the product or its formulation. It is also very important that the preservatives do not cause any toxicology problems. (Toxicology is important in testing, but it is not the focus of this chapter.)

The United States has prohibited or severely restricted (Steinberg 2012):

1. Hexachlorophene
2. Mercury compounds
3. Bithional
4. Halogenated Salicylanilides

Canada has established a "hot" list of cosmetic ingredients that are either prohibited or restricted (Steinberg 2012).

Let us turn our attention to six factors that encourage microbial growth in products. They are:

1. Water content
2. Available nutrients
3. pH values
4. Osmotic pressure
5. Surface tension
6. Temperature

Water Content

It would seem that honey would be an ideal growth medium for bacteria and fungi in that it contains much water and sugar. The interesting point is that honey does not need preservatives. The reason is that the sugar and water are tightly bound to each other, so that they are not available to microorganisms for growth. So it is important that one distinguish between water content and available water or water activity in a solution.

Water activity can be written as "a_w" and defined as the ratio of water vapor pressure of a product compared to pure water at the same temperature (Steinberg 2012).

$$a_w = \frac{p}{p_0}$$

where:

p = vapor pressure of the solution

p_0 = vapor pressure of pure water

The water activity of a solution can be determined by (Steinberg 2012):

$$a_w = \frac{n_2}{n_1 + n_2}$$

where:

n_1 = number of molecules of solution

n_2 = number of molecules of water

Because this is a ratio of vapor pressures, activity is not a strong function of temperature. It is defined as the vapor pressure of a liquid divided by that of pure water at the same temperature; therefore, pure distilled water has a water activity of exactly one (Steinberg 2012).

Equilibrium relative humanity (ERH) is:

$ERH = a_w \times 100$

Measuring Water Activity

There is no device on the market at this time that can measure water activity directly. Presently, it is measured from the relative humidity in the air surrounding the sample after both the air and water samples are at equilibrium (Steinberg 2012).

Water activity is one of the most critical factors in determining the quality and safety of goods marketing to consumers across a wide range of market concerns (Steinberg 2012). Water activity affects the shelf life, texture, flavor, and the odor of products used in the cosmetics industry. While temperature, pH, and other factors can influence if and how many microorganisms can grow in the product, water activity is an important factor in spoilage.

Most bacteria do not grow in water activity below 0.91, and most molds do not grow in activity below 0.80 (Steinberg 2012). By measuring the water activity, it is possible to predict with some degree of accuracy which microorganisms will and will not be a potential product contaminate.

Water activity, not water content, can deliver the lower limits of available water for microbial growth. It can also play a significant role in determining the activity of enzymes and vitamins in the finished product (Steinberg 2012). This can have a big impact on the color and aroma of the product.

Typical Water Activity

Product	a_w
Shampoos	0.97
Conditioners	0.96
Liquid Soap	0.91
Hand Cream	0.86
Hand Lotion	0.98

Microorganisms		a_w*
Fungi	*Aspergillis niger*	0.77
	Candida albicans	0.87
Bacteria	*Staphylococcus aureus*	0.86
	Escherichia coli	0.95
	Pseudomonas aeruginosa	0.97

* Minimum needs

Some microorganisms seems to growth with water activity (a_w) as low as 0.70, so it is a good rule that the water activity needs to be below this level or the product will need some chemical preservatives (Steinberg 2012). As can be observed, most products have a higher a_w than fungi, and a chemical preservative is necessary.

Available Nutrients

If there are available nutrients, such as carbohydrates, proteins, and phospholipids for microorganisms, then preservatives must be utilized. Many microorganisms hydrolyze the linkages or certain monoionic surfactants that then allow nutrients to be ingested and the bacteria or fungi to grow (Forbes, Sahm, & Weissfeld 2002; Joklik, Willett, & Amos 1984). The rule of growth can be very high, depending upon the microorganisms that contaminate the product; usually, it is multiple microorganisms, both bacteria and fungi, if there is no preservative.

Anionic surfactants are also able to act as sources of food for microorganisms. The chemical structure of the components in the finished product contributes to the susceptibility for certain microorganisms that are capable of oxidizing terminal methyl groups to carboxyl groups in the system (Forbes, Sahm, & Weissfeld 2002).

Many vegetable gums that are utilized as product thickeners can be converted to nutrients by microorganisms (Lundov, Moesby, Zachariae, & Johansen 2009).

pH Value

Microbial growth occurs optimally at a neutral pH (pH = 7). Most bacteria and fungi can grow between pH 5–8 (Lundov, Moesby, Zachariae, & Johansen 2009). If the product constituents can be increased to pH 9 and above, many microorganisms become impaired. The same thing happens when the pH becomes more acidic, or lower than 7.

The pH value of a product's various attributes affects the degree of ionization of useable materials. This can influence the electrical charge of the fungi and both gram-negative and gram-positive bacteria. It also has the ability to modify enzyme production and activity, which regulates the growth of the cell structure.

The growth tolerance limits of pH differ widely in microorganisms. The pH should not be considered a sole cause of microbial growth but a contributing factor. The gram-negative *Pseudomonas spp*. can grow over an extremely large range of pH values, from 3 to 11 (Joklik, Willett, & Amos 1984). Most fungi can exist over a wide range of pH values; some have been known to live in pH 9.

Osmotic Pressure

The permeable membrane surrounding all cells can be ruptured by changes in osmotic pressure. Changes in osmotic pressure also lead the cell membrane in shrinkage and dehydration of the cell (Varvaresou et al. 2009). Osmotic pressure is the availability of water and is described by a_w, which is very important.

Concentrations of 40–50% glycerin and sorbital are inhibitory to almost all types of bacteria and fungi that are of importance in cosmetic products. Very concentrated aspects of products are more self-preservative, meaning their physiochemical properties do not permit growth. If a product is diluted with water, it may become susceptible to spoilage. Shampoos that are frequently sold to professional hairdressers can become degraded.

Surface Tension

Many gram-negative bacteria, coliform in particular, grow very well in the presence of surfactants. Most gram-positive bacteria do not grow well at surface tension levels below 50 dyn/cm. Gram-negative microorganisms such as *Pseudomonas spp*. and coliforms (e.g., *Cornebacterium sp*.) may grow well in shampoos and conditioners (Al-Hiti & Gilbert 1980). Cationic surfactants are toxic to many microorganisms, but anionics to just a few. Nonionics are not lethal to microorganisms.

Microorganisms that contribute to cosmetic product spoilage often are aerobic and anaerobic, depending upon the availability of oxygen for their metabolism (Lambert & Stratford 1999). The oxygen tension of most cosmetic products promotes sufficient oxygen for growth of microorganisms.

Temperature

Temperature plays a significant role in microbial growth. Most cosmetic products are not stored in ideal conditions, often in growth-promoting temperatures (Beales 2004). For example, mascara may be put in a purse or left in a car. If it is in a hot climate or stored in a car that can really heat up, spoilage by chemical breakdown and microorganism growth can easily occur. The ideal temperature for many bacteria is 30–40°C and, for fungi, 20–25°C.

Necessity of Preservatives

In previous times, many microorganisms have been found in cosmetic products both new and unused, and used (Beales 2004). It seems that it was not a bacterial or fungal infection, but a degradation of the product that caused preservatives to be used.

The main requirements for selecting a preservative are (Paulson 2013):

1. Noninterference of the cosmetic product's action or mode of activity
2. Freedom from causing negative attributes, such as products' odor, color, and feel
3. Does not cause toxic or irritating effects to the end user
4. Can cause longer storage than the product alone
5. Is stable to moisture, heat, and dryness
6. It must have activity at low concentrations.
7. It must be effective over a wide range of pH values.

When a compound is manufactured, its various components are unbalanced to give it, for example, cleaning ability. If preservatives are not present, the compounds break down into stable but less active structures. The product then loses its potency. This is also why preservatives are necessary.

4.1.7.13 PROBLEMS WE FACE WITH THE USE OF PRESERVATIVES

To situate preservatives in the industry and society, let us first discuss the quadrant system, which will explain our individual and social perspectives.

The Quadrant System

To better understand this topic, let us overlay this onto a four-quadrant system (Paulson 2002; Wilber 1995). You might ask, "What is the four-quadrant system?" It consists of the complete sphere in which you live, from the personal to the world of consumers in the subjective and objective components (2, 3). The four-quadrant system, then, consists of the objective and subjective components of you and the consumers who purchase your product. This is normally seen in four different paradigms (Kuhn 2012). At least two quadrants (the subjective quadrants) are suppressed

from our lives, but they exist and contribute to a product's success. Science has disassociated the entire subjective viewpoint, stating that only the physical is real. We will reintegrate these four paradigms into one megasystem—the quadrant view.

You

Subjective	- Your likes and dislikes - Prejudices - How you live your life	- Your objective view
	- Culture (what they like, will buy, and why they buy)	- Society (Rules, laws, and legislature)

Objective

Consumers

The top two components, consisting of "you," subjective and objective, are what I will first discuss. The top layer could also be another person, depending on the perspective. But as this chapter is read by you, it will be from "your" perspective. The upper right quadrant is how you can touch, see, and view the objective world. It is what is called "reality" for many people, for they do not see any of the other quadrants. It is their conscious scientific attitude. The other three quadrants are collapsed—unknowingly—into this one quadrant in our modern world, where the subjective, cultural, and societal quadrants are ignored. However, in reality, the four quadrants occur simultaneously in our lives.

The upper-left quadrant is the one in which we have our subjective experiences. For example, it tells us what we like and do not like. It tells us what we fear, what we appreciate, and describes our need for companionship with others close to us (Campbell, 1976; Mitchell & Black 1996). It contains the conscious, preconscious, and unconscious aspects of our selves. Our conscious aspects are those of which we are aware. Also, they are the areas that we prefer, such as the scent of a cologne, the feel of a skin moisturizer, and what we buy to feel secure. Our preconscious is our monitor. It does not let things that are not considered acceptable by our culture into our conscious. The unconscious is what is suppressed, repressed, and denied. It is also the quadrant that determines if a person will buy the product based on subjective experience. This includes ease of use, odor, color, size, and feel of the product, etc.

The lower-left quadrant represents the culture. It is extremely important, but often it is ignored. It contains the cultural beliefs shared by a society, and the shared values, such as the feel or fragrance of a product preferred by others, which has great influence on customers. These values are generally of two types: manifest

and latent (Newman 1997). Manifest are surface values that are conscious to the consumer. For example, your product may be on sale, so it is discounted and that is a reason for purchasing it. But deeper, more fundamental values are also present. These are referred to as latent values, which are generally unconscious to the consumer. The smell of the product may activate a memory of the person being younger and in love. Therefore, s/he buys the product with these unconscious needs as the driving force. What consumers believe to be true, then, is not necessarily grounded in reality. This should be remembered when using preservatives. If your product is degraded and spoiled at the time of use, it can affect future product sales.

The lower-right quadrant represents society. A society has rules and laws to follow—regulations that go into making your product. These societal requirements include conforming to regulation agency standards, which include the Food and Drug Administration (FDA), Federal Trade Commission (FTC), and the Environmental Protection Agency (EPA), as well as the rules, laws, and regulations they enforce. So before designing a product, it is important to fully understand the current legal regulations governing the product preservative components and their maximum levels.

The four-quadrant approach is important also, in that it is viewed as a system of four components that occur in the four areas of the preservative system. For example, let us look at a shampoo product. In the upper-right quadrant, we use it to clean our hair. If the preservative was not present, the shampoo could begin to break down. The first thing that could happen is color and odor change, while its basic cleaning chemistry components would not be as precise.

The antimicrobial aspects could begin to break down, allowing microorganism growth in the formula (Fassihi, 2001). A person would begin to notice a difference; it is not the same.

From a personal, subjective perspective, a person would now question the product's value. Perhaps a consumer would ask questions like "Does it smell the same?" "Does it feel different?" This will go on until the person finally says, "Something is wrong with this product." Instead of getting the aesthetic of "feeling springtime fresh," the person feels as the "winter doldrums." The values shared with others, both manifest and latent, are constantly changing. The conscious aspects—manifest values—of springtime freshness are changing. But the deeper, more fundamental value of being clean, and therefore being accepted and valued as a worthwhile person, are being unconsciously challenged. Maybe they support the notion that the person is now unclean and will be rejected as a worthwhile person. This causes the person to be unconsciously open to purchasing other shampoos.

This plays into how a person judges the things s/he buys based upon the culture. The lower-left quadrant contains all the information on which we act and should act in a culture from that culture's perspective (Paulson 2002; Wilber 1995). We know that this is where we place the feelings that we have compared to what our

culture has determined. So when we feel a "springtime fresh feeling," we compare it to coolness, the brilliance and lasting good smell and the renewed feeling we enjoy from the springtime. However, if the product and our conception of it are at odds, we feel bad.

The product failed to meet our cultural standards. We do not feel valued, loved, or appreciated by the people who are close to us or others. We must find something else to make us feel the connection.

The lower-right quadrant is the society with its rules and regulations (Paulson 2002; Wilber 1995). The Cosmetics, Toiletries, and Fragrance Association (CTFA) and the Soap and Detergent Association (SDA) are the two big regulators in this area. But there are others. For example, the FTC and interstate laws govern these product supplements as well. If the products' ingredients decomposed, a firm could be vulnerable to a lawsuit. For example, the product could be said to have caused facial damage or damage to the consumers' children.

These quadrants are all important, but for the sake of brevity, we shall focus on the lower-righthand quadrant in this chapter. In this quadrant, the percentage of a preservative and the exact components are provided. Preservatives are included in products to greatly slow the products' spoilage rate and microbial contamination (Fassihi 2001). The aesthetic appeal and functionality are also addressed.

CONCLUSION

In this chapter, the basics of preservatives have been discussed. This is not enough to finish a successful product, but it will help as you begin to look at a potential preservative and then make choices.

ANTIOXIDANTS: EXTENDING THE SHELF LIFE OF YOUR PRODUCTS

Author

Kemin Industries,
2100 Maury Street, Des Moines, Iowa

ABSTRACT

Antioxidants are being used for several purposes in the personal care industry, ranging from prevention of rancidity in formulations to sun protection and prevention of skin aging. These materials are generally used to neutralize free radicals, which may result from improper storage of the formulation or environmental stress on the skin.

Oxidation in formulations is a result of the generation of free radicals that convert unsaturated fatty acids in the contained oils into undesirably odoriferous molecules. These free radicals can be generated by heat, light, and metal ions. Antioxidants quench the formation of these free radicals, thereby reducing the rate of oxidation and subsequently increasing the shelf life of the product.

Traditionally many synthetic antioxidants have been used for the above-mentioned applications. However, due to heightened consumer awareness and toxicity questions, many of these synthetic ingredients have come under scrutiny. The cosmetic and personal care industry has responded to these issues by seeking and finding materials better suited to address these issues. There are several plant-based antioxidants available that can perform as well or better than their synthetic counterparts in these applications. This chapter will focus on various applications of natural antioxidants in extending shelf life of formulations.

4.1.7.21 INTRODUCTION

Oxygen, despite being necessary for sustaining life, is also detrimental in many aspects. The damaging effects caused by the ubiquity of oxygen have been classified as "oxidation reactions." Some of the common negative observations attributed to oxidation include: browning of fruits and vegetables over time, rusting of iron, and even aging. One of the principle causes for the reduction in shelf life of cosmetic products is oxidation of unsaturated oils. Unprotected cosmetic products, when exposed to environmental factors such air, light, and high temperatures, are susceptible to oxidative degradation. This process results in discoloration, off-odor, and also physical instability of the products.

The oxidative-degradation products include peroxides and hydroperoxides. These products are not the primary source of the debilitating effects observed in the formulations, but rather, it is their degradation products such as aldehydes and ketones that cause undesirable visual and sensorial changes in the formulation. [1] [2] Although the mechanisms responsible for lipid oxidation have been studied extensively, as of yet they are still not fully understood. The rate at which oxidation of lipids occurs and the pathway it follows depends upon several factors such as the degree of unsaturation, the presence of other components in the system, and the physical state of the system. [3]

Antioxidants have become an indispensable group of additives to cosmetic formulations. [4] They not only effectively retard the onset of oxidation in products but can augment the consumer's natural topical defense system against oxidation. Most antioxidants are phenolic compounds, which have the ability to donate a hydrogen free radical easily and in turn get oxidized. [5] Both natural and synthetic antioxidants have been used in cosmetic products to improve their shelf life. [6] Many currently used synthetic antioxidants have been under extensive scrutiny due to concerns over their safety. In addition to this concern for safety, consumers

are becoming more aware of the sources of ingredients being used in their personal care products and are demanding that they be obtained from natural, sustainable, and safe sources. Plants produce a variety of complex phenolic compounds to protect their internal "machinery" from oxidation. Some of these plant-based molecules exhibit remarkable antioxidation capabilities rivaling those of their synthetic counterparts.

Several key factors need to be taken into account to choose the right antioxidant for a particular system. The most important ones are: the oil component of the system; polar or nonpolar oils; potential impurities in the ingredients used, such as metal ions; physical state of the formulation; gels, oils, emulsions, etc.; desired shelf life of the product and manufacturing process; heated or cold processing.

Numerous assays have been developed to determine efficacy of antioxidants. These assays vary from measuring the kinetics of lipid peroxidation to measuring the primary and secondary oxidation product. Since many of these assays are not conducted in the final formulation, care should be taken in interpreting the obtained data. Regardless, these assays are good tools in providing insights concerning feasibility of the antioxidant.

The overall goal of this chapter is to provide the reader with an understanding of oxidation, how it affects a formulation, and how antioxidants can be used to improve the shelf life of a cosmetic or personal care product.

4.1.7.22 OXIDATION

The phenomenon of oxidation is defined as loss of electron by a molecular species. The rate for a molecule to undergo oxidation depends on the activation energy needed to abstract an electron or a hydrogen free radical from it, which in turn depends on its molecular structure.

Mechanism of Lipid Oxidation

The basic mechanism of lipid oxidation has been very well characterized. This process can be divided into three distinct steps: Initiation, Propagation, and Termination. [3] [7]

Initiation

Auto-oxidation of unsaturated lipids is thought to be initiated by free radicals, which can be generated by heat, metals, or other impurities; and enzymes and light in presence of oxygen. [8] In this process, the a-carbon atom to the double bond loses a hydrogen free radical and forms a lipid radical (Figure 1).

Figure 1. Generation of lipid free radical by abstraction of hydrogen free radical from unsaturated lipids.

It is well characterized that polyunsaturated fatty acids are more susceptible to free radical oxidation than monounsaturated fatty acids. Table 1 illustrates the amount of energy required to abstract hydrogen from different carbons of linoleic acid. Hydrogen from position 11 is most easily removed due to the double bonds on either side of that c-atom. [8]

Table 1. Energy required for removal of hydrogen atom from different positions of c-atoms in linoleic acid.

Hydrogen Removal Position	Energy Required (kcal/mol)
	50
	75
	100

Lipid radicals can also be generated by addition of free radicals to the double bonds of unsaturated lipids (Figure 2). [9]

Figure 2. Generation of lipid radical by addition of free radical to unsaturated lipids.

Light-induced initiation or photo-oxidation occurs in the presence of oxygen and a photo-sensitizer molecule such as chlorophyll or other electromagnetic radiation–absorbing species. In photo-oxidation, light excites the sensitizer molecule to its triplet state (^{3}Sen*). This excited molecule then induces oxidation by one of the two mechanisms known as Type I or Type II. Figure 3 illustrates the general pathway for the two mechanisms. In Type I, the excited sensitizer can directly interact with the lipid molecule to generate lipid radicals which in turn starts a free-radical chain reaction, where the lipid radical can react with triplet state oxygen ($^3O_2$) to form peroxyl radicals (ROO*). In this case, the rate of reaction is dependent on the concentration and the type of sensitizer and substrate i.e. lipid molecules. In Type II, the excited sensitizer can interact with molecular oxygen, which is in triplet state, to form high-energy singlet oxygen species ($^1O_2$). The singlet oxygen can then react with lipid molecules to form hydroperoxides (ROOH). The rate of reaction for Type II pathway is primarily dependent on concentration and solubility of oxygen in the system. The resulting hydroperoxides can further dissociate into free radicals. [8]

Figure 3. Light-induced initiation and reaction with the lipid molecule via Type I and Type II pathway.

Metal ions, such as Fe^{+2}, Cu^{+2}, and Co^{+2}, can also initiate formation of free radicals by reacting with lipids (Figure 4). The generated free radical can then initiate a chain reaction. [10] [11]

$$RH + M^{+2} \longrightarrow R^{\bullet} + H^{+} + M^{+}$$

Figure 4. Metal ion-induced initiation and reaction with lipid molecules.

The activation energy for generation of free radicals can also be supplied by heat or by the presence of enzymes. High temperatures during processing of oils can initiate the free-radical chain reaction and can lead to oxidative degradation of oils. Also the presence of enzymes in a system such as lipoxygenases or any hydrolytic enzymes can reduce the activation barrier for generation of free radicals.

Propagation

The free radicals generated during the initiation step react with other molecular species in the system to form new free radicals in the propagation phase. This sets off a chain reaction where multiple species of free radicals are generated in the system (Figure 5). Lipid free radicals can react with oxygen to form lipid peroxyl radicals (ROO*), which in turn can react with other lipid molecules (R_1H) to form lipid hydroperoxides (ROOH) and lipid free radicals (R_1*). Hydroperoxides are unstable and can degrade to produce other free radicals such as lipid oxy radical (RO*) and hydroxyl radical (OH*). [3]

Figure 5. Generation of multiple free radical species during the propagation phase.

The propagation reaction is repeated many times and continues as long as unsaturated lipids are available. The chain reaction nature of this phase results into accumulation of hydroperoxides. The hydroperoxide species generated in the system are dependent upon the molecular structure and the unsaturation level of

the lipid. Lipid hydroperoxides are primary products of oxidative degradation and are odorless. [12]

Termination

Lipid free radicals are structurally unstable and are highly reactive species. Since the free radicals have an unpaired electron, they are constantly seeking to pair that electron with other molecular species. During the propagation phase the number of unsaturated lipids is decreasing, as they are being consumed by free radicals to form new free radicals. This results in a free radical–rich system where the free radicals bond with one another to form astable nonradical species, which results in termination of the propagation cycle. Figure 6 illustrates the different ways in which lipid free radicals are terminated.

Figure 6. Multiple reaction pathways by which free radical reactions are terminated.

The stable species generated during the termination step are considered as secondary products of oxidative degradation and most often are carbonyl compounds (aldehydes, ketones, or fatty acids). It is the presence of these reaction products that affects the sensory profile of the product, most often detected as off-odor and off-color. [12]

4.1.7.23 ANTIOXIDANTS

A simple definition of an antioxidant is a compound that opposes oxidation. Antioxidants are sacrificial molecules that undergo oxidation and slow down the oxidative damage done to the other molecules. [12] They tend to slow down oxidative reactions by inhibiting or retarding any or all of the three steps of auto-oxidation: initiation, propagation, and termination. The use of antioxidants is prevalent and necessary in cosmetic formulations, particularly the ones that use lipids. The shelf life of a product can be improved substantially by using the right antioxidants.

Antioxidants can broadly be classified under two categories: Primary and Secondary antioxidants. Molecules that are capable of quenching free radical species and thereby delaying or inhibiting the initiation step or slowing down of the propagation step during the auto-oxidation cycle are termed "primary antioxidants." Secondary antioxidants are compounds that slow down the oxidation reaction but by means other than just free radical quenching. [12] [11]

Figure 7 depicts the various free radical species that primary antioxidants (AH) can react with to form stable molecules and hence slow down the chain propagation and eventually the overall oxidative damage to the system. Primary antioxidants are typically phenolic compounds that can donate a hydrogen radical to the free radical species. In this process they reduce the primary radicals to non-radical species and in turn get converted to oxidized antioxidant species. Efficacy of an antioxidant depends on its molecular structure. Efficacious antioxidants can not only donate hydrogen radicals but can themselves form radicals that have low reactivity and low possibility of reacting with lipids. [11]

Figure 7. Reaction of antioxidant (AH) with a variety of free radical species generated during the auto-oxidation of lipids.

4.1.7.24 PRIMARY ANTIOXIDANTS

Synthetic Antioxidants

One of the most common synthetic antioxidants used in cosmetic formulations is butylated hydroxytoluene (BHT). [11] The stability of the free radical–reacted antioxidant depends on its structure and the number of resonating free radical structures it can form to stabilize that free radical. [13] Figure 8 illustrates the structure of BHT and the different resonating structures it forms during the stabilization of the free radical. The large number of resonating structures that BHT can form with free radicals makes it a potent antioxidant in an "oil-heavy" formulation.

Figure 8. Resonating structures that butylated hydroxytoluene (BHT) forms to stabilize free radical.

In addition to BHT, butylated hydroxyanisole (BHA) and *tert*-butylated hydroquinone (TBHQ) (Figure 9), are other synthetic antioxidants that have also been used in personal care formulations to prevent rancidity. [7] BHA is a mixture of two isomeric forms that are produced during its synthesis.

Figure 9. Structures of two isomers of butylated hydroxyanisole (BHA) and *tert*-butylhydroquinone (TBHQ).

Over the past two decades, there has been a shift away from synthetic ingredients towards more natural products. This shift stems from the need of the consumer to understand sources and the environmental impact of the ingredients that are being used in the products that they consume. Another popular belief, though not always true, that everything natural is safe, has led to the ingredient research in finding natural alternatives to synthetic ingredients. This shift has also led to the decline in the demand of many commonly used synthetic ingredients, such as BHT. In addition to the consumer trend, there are also some regulatory limitations being imposed on the use of certain synthetic ingredients. These events have led to an increase in the use of natural ingredients, especially the ones derived from plants.

Natural Antioxidants

Nature is considered to be a highly efficient "chemist," with plants being its reaction vessels, producing molecules with such a high degree of complexity that they could never be reproduced economically outside of those plants. Plants can be considered as "factories" that can produce molecules that have applications in variety of fields. Fine chemicals produced from plants can truly be considered as renewable products because plants harvest light, air, and water to produce these molecules. Once the molecules of interest are extracted out of the plant, the spent biomass can be returned to the environment and recycled. Several botanicals have been used in cosmetic formulations that have been known to prevent lipid oxidation. [14] Two of the most common ones are nonpolar extract of rosemary and tocopherols obtained from vegetable oils and their derivatives.

Tocopherols are a class of compounds that have a chromanol ring and a phytyl chain. They exist in four different forms (Figure 10). [15] [16] Vitamin E activity of tocopherols has been mostly attributed to a-tocopherol. [17] Among

the different homologues of tocopherol, the antioxidant activity is in the following order: d-tocopherol > g-tocopherol > b-tocopherol ≈ a-tocopherol. [18] [19] [20] Use of a-tocopherol or vitamin E has been successful in preventing lipid oxidation at low concentrations; at higher concentrations it was found to be either neutral or pro-oxidant. [21] [22] [2] This dualistic behavior of a-tocopherol can be attributed to its inability to stabilize free radicals for long enough periods before the molecule itself becomes a free radical donor. The pro-oxidant mechanism of a-tocopherol is depicted in Figure 11. The a-tocopheroxyl radical formed can donate a free radical to other lipid molecules (RH) or lipid hydroperoxide (ROOH), where it can re-initiate the auto-oxidation of lipids and thereby act as a pro-oxidant. It is important to note that even though vitamin E might be used in a formulation for its skin benefits, if used at improper concentration it can reduce the shelf life of the formulation by pro-oxidizing the lipids. The pro-oxidant effect of vitamin E at high concentrations can be nullified by using co-antioxidants in the system.

Derivatives of tocopherols have also been used in cosmetic formulations. Most common derivatives are tocopheryl acetate and tocopheryl palmitate (Figure 12), where the hydroxyl group on the chromanol ring is esterified with a fatty acid. Esterification of the hydroxyl group stabilizes the tocopherol in the formulation but also strips away any proton-donating antioxidant activity of the molecule. It is believed that the ester hydrolyzes over time once it is absorbed in the skin and frees the tocopherol. [23]

Figure 10. Structures of different forms of tocopherol.

Figure 11. Pro-oxidation mechanism of a-tocopherol in a lipid system.

Figure 12. Ester derivatives of a-tocopherol.

Rosemary extract has been commonly used in variety of food matrices to prevent lipid oxidation. [3] Its usage in cosmetic formulations has been increasing over the past few years. [24] The extract is obtained from the leaves of the plant *Rosmarinus officinalis*. Most industrial-scale processes use organic solvents such as acetone, hexane, or methanol to extract the key antioxidant molecules from the leaves. Due to increasing trend towards natural products and certifications, many of the listed solvents are being replaced by supercritical carbon dioxide because of its acceptability as an extraction solvent for naturally processed ingredients. The nonpolar extract of rosemary leaves contains a class of molecules called phenolic diterpenes. [25] [26] The antioxidant activity of the rosemary extract has been mostly attributed to the two most prominent phenolic diterpenes: carnosic acid and carnosol (Figure 13). [27] The primary purpose for the production of these antioxidant molecules in the plant is to protect the photosynthetic pathway of the plant from oxidation. [28]

Figure 13. Structures of carnosic acid and carnosol found in rosemary extract.

Rosemary also yields an essential oil fraction, obtained by steam distillation, which is used for its fragrance and aromatherapy. [29] [30] This fraction has little to no contribution towards preventing lipid oxidation. Essential oils primarily consist

of terpenes such as camphor, 1,8-cineole and verbenone (Figure 14). [29] Terpenes are volatile compounds that contribute to the odor of the plant and are devoid of hydrogen radical donating property such as that found in other effective antioxidants.

Figure 14. Common terpenes found in rosemary essential oil.

Phenolic diterpenes are known to sequester free radicals efficiently because they can form other g-lactone phenolic diterpenes that have antioxidant activity. Carnosic acid on interacting with a free radical can undergo rearrangement and form carnosol, which is also an antioxidant. [31] [3] [9] The oxidation of carnosol results in the formation of rosmanol, which can then further oxidize into gladosol (Figure 15). The formation of successive antioxidants by oxidation of these phenolic diterpenes renders them an exceptional antioxidant capacity that can rarely be matched by any synthetic antioxidant where, upon oxidation, synthetic antioxidants are converted into an inactive form. The complexity and redundancy that nature has put into such molecules to counter oxidation can rarely be found outside of the plant kingdom.

Figure 15. Rearrangement pathway that carnosic acid undergoes during an oxidation cycle that produces subsequent antioxidants.

One of the challenges of using natural plant extracts in cosmetic formulation is the impact they can have on the organoleptic properties of the product. The herbal odors and colors imparted by the natural product can often limit their inclusion levels in the final product to ineffective amounts. For example, an organic solvent–extracted rosemary product will also have an essential oil fraction of the plant. To remove this odor, a secondary processing step needs to be included, such as distillation. But the resulting product will still have substantial color that can have an impact on the final product. Recently, a few low-odor and low-color rosemary products have emerged in the market that have low to no impact on the organoleptic profile of the final product. To achieve such a product, a secondary process is implemented that concentrates the molecule of interest in the extract and removes inactive molecules such as terpenes and chlorophyll. To develop such processes it is important to understand and identify the active molecule for the intended application in the formulation.

4.1.7.25 SECONDARY ANTIOXIDANTS

Secondary antioxidants reduce the rate of oxidation of lipids by several pathways, such as binding of metal ions, neutralizing singlet oxygen species, and scavenging of oxygen. [12] [11] One of the biggest limitations of using only the secondary antioxidants is that their mechanism of action is very specific while auto-oxidation of lipids is a combination of several different types of reactions. They are most effective when used in conjunction with primary antioxidants.

Metal ion chelators such as ethylenediaminetetraacetic acid (EDTA) or citric acid are extremely important in preserving the systems that have high water activity such as oil-in-water emulsions, soaps, and shampoos. In such systems, metal ions—which are more soluble in the polar phase—may diffuse into the water/oil interface and can initiate auto-oxidation of lipids. Chelation of metal ions results into neutralization of their charge and subsequently their ability to initiate auto-oxidation of lipids. [32] Figure 16 depicts general reaction schemes for EDTA and citric acid with metal ions.

$$M^{+2} + [EDTA]^{-4} \longrightarrow [M\text{-}EDTA]^{-2}$$

$$M^{+2} + [CITRATE]^{-3} \longrightarrow [M\text{-}CITRATE]^{-1}$$

Figure 16. General reaction scheme for chelators reacting with metal ions.

Alternatives to synthetic ingredients such as EDTA are being sought due to the rise in demand for plant-based natural ingredients. Citric acid, although it is a natural chelator obtained by fermentation, is not as strong as EDTA, which limits its use. Phytic acid or its salt form, sodium phytate, obtained from bran of rice,

wheat, or corn, is a strong chelator. [33] It is an inositol hexakisphosphate with six phosphate units bound to an inositol ring (Figure 17).

Figure 17. Structure of phytic acid (R) and its sodium salt (R').

Another natural chelator that has been used extensively in cosmetic formulations is gluconic acid and its derivatives (Figure 18). These molecules have been found to chelate di- and trivalent metal ions. [34]

Figure 18. Structures of various gluconic acid derivatives.

One of the most common oxygen scavengers or reducing agents used in cosmetic formulations is vitamin C or ascorbic acid. [35] Ascorbic acid can react with oxygen to form dehydroascorbic acid and hydrogen peroxide (Figure 19). [36] [37] This formation of hydrogen peroxide can further exacerbate the oxidative stress on the system. The three carbonyl units on dehydroascorbic acid render it highly reactive and can participate in a Maillard reaction and impart a brown color to the formulation. [38] To avoid complete oxidation of ascorbic acid, it is often used along with a primary antioxidant that can regenerate ascorbic acid from its oxidation products. [39]

Figure 19. Oxidation of ascorbic acid to dehydroascorbic acid.

Another class of compounds that have been used as secondary antioxidant is carotenoids. [40] They can quench high-energy singlet oxygen. [8] In the presence of carotenoids, singlet oxygen will preferentially transfer its excess energy to the carotenoid species present in the system to produce a triplet-state carotenoid. The excess energy of the triplet-state carotenoid is then given off as heat as it returns to ground state (Figure 20). Carotenoids are effective quenchers of singlet oxygen. One carotenoid molecule can quench numerous singlet oxygen molecules.

Figure 20. Singlet oxygen quenching by carotenoids.

The ability of carotenoids to quench singlet oxygen is directly related to the number of double bonds in the compound. Carotenoids with more conjugated double bonds are more effective quenchers. [41] Some of the common carotenoids used are b-carotene, lutein, lycopene (Figure 21). [42] Since all these molecules have conjugated double bonds, they have an intense orange to red color that is imparted to the final formulations. This coloring ability limits the type of formulations in which these molecules can be incorporated, being primarily color formulations.

In addition to the singlet oxygen quenching, these molecules have several skin benefits. For example, lutein has been shown to improve skin moisturization and elasticity, and also provide photoprotection. [43]

Figure 21. Structures of common carotenoids used in cosmetic formulations.

4.1.7.26 ANTIOXIDANT ASSAYS

Antioxidant ability of ingredients can be evaluated by several means. Some assays measure the relative ability in just oils, since oils are the primary component of a formulation susceptible to oxidation; others measure retardation of the oxidative damage in a finished formulation. In this section, few of the common methods to assess the efficacy of antioxidants in improving the shelf life of the formulation will be discussed.

There are also other methods, not discussed in detail, particularly 2,2-diphenyl-1-picrylhydrazyl (DPPH) and Oxygen Radical Absorbance Capacity (ORAC) assays that are used for screening antioxidants. [44] These assays can provide relative antioxidant capacities of an ingredient, but disputes have arisen due to the lack of correlation between these assays and their ability to predict performance of an ingredient in a finished formulation. The primary reason for this disagreement stems from the fact that the matrices for cosmetic formulations are complex in comparison to the ones used in these assays. [3] The antioxidant activity depends on several factors such as media, temperature, nature of oxidants, and microenvironments in the formulation and not only on free-radical quenching ability of an antioxidant, which is what DPPH and ORAC primarily predict. These assays cannot predict the pro-oxidant effect of antioxidants. It is well known that certain antioxidants exhibit a concentration-dependent pro-oxidant effect in a lipid-rich matrix. Since the matrix used in DPPH and ORAC assays is an organic solvent to dissolve the dye, the potential for pro-oxidant effect of an antioxidant cannot be determined using these assays. Extreme care should be taken when using these

assays for predicting antioxidant ability in a formulation, and the observed effects should be corroborated with the more traditional assays described below.

Oxidative Stability Index (OSI)

OSI, also known as the Oil Stability Index, is an official method of American Oil Chemists' Society (AOCS) [45] and is well accepted throughout the industry in predicting antioxidant ability of an ingredient in oil. [46] The basic principle of this technique involves measuring the time it requires for a sample to undergo rapid oxidation under accelerated conditions. This time point is then referred to as Induction Period (IP).

In this assay, the sample is heated to a set temperature and is held at that temperature for the duration of the study. To accelerate the oxidation, purified air is bubbled in the sample, which results in oxidation of the sample. The sample then starts to produce oxidative degradation products such as peroxides first, followed by aldehydes and ketones, which are secondary degradation products. Upon further oxidation, the samples produce volatile fatty acids (VFAs). These VFAs are then carried by the air into a water reservoir, where they dissolve and change the conductivity of water.

A conductivity probe immersed in the water reservoir is then used to continuously measure the change in conductivity. The time point at which the rate of change in conductivity increases rapidly is known as the IP. The IP depends on several factors such as the oil or blends of oils used in the study, the unsaturation level of the matrix, the presence of any impurity, presence of an antioxidant or a pro-oxidant in the oil, and the temperature at which the study is being conducted. To study the effect of an antioxidant on the oil(s), a control sample without any additive is also subjected to the test along with the antioxidant treated samples. An ingredient that is an efficacious antioxidant will have a longer IP than the control sample, while a pro-oxidizing ingredient will have a shorter IP. The ratio of IP of a treated sample to that of the control is often used for comparative purposes and is called as Protection Factor (PF). A control will always have a PF=1, while an efficacious antioxidant will have a PF > 1 and a pro-oxidant will have a PF < 1.

As most OSI studies do not last for more than 30 hours, an OSI study could be used as a preliminary test to time-consuming stability studies. OSI could be conducted either on the individual oils that make up the formulation or on the blend of oils. The results from these studies could be used for determining the stability of the different oils, predicting improvement in shelf life of oil and hence the formulation and cost-benefit analysis of adding an antioxidant.

Peroxide Value (PV) Test

Peroxides and hydroperoxides are generated during the propagation phase of auto-oxidation. Peroxides are considered to be the primary

oxidative degradation products (Figure 5). The measurement of peroxides in a system is a good indicator of the oxidative stress a system is undergoing. Unlike OSI, which is used only for oil samples, PVs can be determined in both the oil and/or in a final formulation. The oxidative stress could be imparted in real time or accelerated by incubating the samples at higher temperatures (30–45°C).

PV is typically determined by Iodometry, which is a standard AOCS method (Figure 22). [47] In this method, peroxide (ROOH) is reacted with iodide ion (I^-) to generate iodine. The generated iodine is then titrated with sodium thiosulfate ($S_2O_3^{2-}$) with starch solution as an indicator where it changes from blue/black to colorless, marking the endpoint of the titration.

$$ROOH + 2I^- + H_2O \longrightarrow ROH + 2OH^- + I_2$$

$$2S_2O_3^{2-} + I_2 \longrightarrow S_4O_6^{2-} + 2I^-$$

Figure 22. Reactions involved in iodometric titration for determining peroxide value.

PV is defined as peroxide oxygen per kilogram of fat or the sample and has been traditionally expressed in the units of milliequivalents per kilogram (meq/kg) of the sample.

Generation and accumulation of peroxides and hydroperoxides do not contribute to the off-odor and off-color of a formulation. It is the secondary products such as aldehydes and ketones generated from peroxides and hydroperoxides that cause a system to turn “rancid” and affect the organoleptic profile of the formulation. [3] Since peroxides are precursors to organoleptic failure of a product, tracking them is a good indicator of onset of rancidity. However, care should be taken in interpreting the data, for in a system that has undergone substantial oxidative damage one may not be able to detect any peroxides because they might have been converted to secondary degradation product. Measuring PVs at that point will serve no purpose in predicting oxidative failure of system, and carbonyl products would need to be measured at that point. Figure 23 illustrates a hypothetical time profile for accumulation of primary (peroxide and hydroperoxide) and secondary (aldehydes and ketones) oxidative products generated in a system. If the measurements for PV were made only at time point A and B, it would give an impression that the system is not undergoing any oxidative stress. However, in reality there is accumulation of secondary products, which would change the organoleptic profile of the system. Hence it is important that frequent PV measurements are made in the initial stages of the study.

Figure 23. Time profile for generation and accumulation of primary and secondary oxidation products in a system.

Measurement of Secondary Oxidation Products

Most of the secondary oxidation products are carbonyl compounds, which are highly reactive towards nucleophiles. Several compounds have been developed to react with these secondary oxidation products, resulting in formation of chromophores which can be measured spectroscopically. A few of these molecules are listed in Figure 24. [48] [49] [1] For many of these assays validated kits can be obtained from various vendors.

Figure 24. Molecules used for detection of secondary oxidation products.

CONCLUSION

Oxidation is one of the major adversities that a cosmetic or personal care formulation faces during its lifetime. It is important to understand the source and mechanism of oxidation and the specific ingredients that are susceptible to this

phenomenon. Since oxidation is a foreseeable thermodynamic eventuality, it can only be slowed down but never stopped completely. Choosing the right antioxidant can help in warding off oxidation for a sufficient period of time and improve the shelf life of the formulation. In addition to choosing the right antioxidant, it is equally important to choose the right assays to measure oxidation and the effect of antioxidants on a system. The chosen assays should provide enough information to understand the right oxidative stress points in the system and also be pertinent to the final application for which the formulation is being developed. For example, if a nonaqueous formulation is being developed, then conducting OSI on a blend of the oils with an antioxidant might be sufficient. If an oil/water emulsion is being developed, then it might be prudent to conduct both OSI on the oils and PV on the final formulation.

There is a concept called the "polar paradox" which states that hydrophilic antioxidants perform better than hydrophobic antioxidants in nonpolar systems such as bulk oils; while hydrophobic antioxidants perform better than hydrophilic antioxidants in polar systems such as oil/water emulsions. [50] [3] Although not completely understood, the explanation for this behavior stems from the belief that oxidation is a surface phenomenon where it is initiated at the interface of the two phases. For bulk oils it is initiated at the oil-air interface, and for oil-in-water emulsions it is initiated in the water phase surrounding the oil droplets. Having an antioxidant at the interface, and not in the bulk, would improve its chances in retarding oxidation of the lipids in the system and hence protect the lipids from oxidative damage. The "polar paradox" does not always predict an antioxidant's performance but is too valuable to be ignored and may help in understanding the anomalous behaviors of antioxidants in a given system.

ABSTRACT

There are many rheological additives a formulator may select to obtain the desired properties of the final formulation. Often several rheological additives would perform well in a particular formulation and the formulator must make some choices. Considerations regarding the product application, labeling, consumer targets, and pricing come into play. However, more important considerations are the requirements of processing and the stresses the formulation will encounter. Therefore, the pH of the formulation, the processing temperature and shear rate, the packaging conditions, and the consumer's handling of the product are extremely important. The formulator must also consider the desired appearance and properties of the final formulation.

Most rheological additives contribute more than controlling basic flow and viscosity properties. Many also provide flow properties, suspension properties, emulsion stabilization, stability to shear, heat, pH, or freeze/thaw cycles, etc. The rheological additives that can be utilized to achieve these properties in various applications are discussed in this chapter, as well as an overview of each of these rheological additive categories.

4.2.1.1 DESIGNING RHEOLOGICAL BEHAVIOR

4.2.1.2 NATURAL AND SYNTHETIC POLYMERS: RHEOLOGICAL PROPERTIES AND APPLICATIONS

Natural and synthetic polymers are used in a multitude of formulations to design rheological properties for various applications. This chapter discusses rheological additives for both water-based systems and anhydrous systems. Rheological additives for water-based systems include natural gums and natural gum derivatives, cellulosics, starch derivatives, clays, polyethylene glycols, fatty alcohols, and polymers. Anhydrous systems are more often modified by the use of silicas, polyethylenes, fatty acids, castor oil derivatives, aluminum/magnesium hydroxide stearate, stearic acid derivatives, or organoclay pre-dispersions. Some of these additives are used for both aqueous and nonaqueous formulations.

Most rheological additives contribute more than basic flow and viscosity properties. Many also provide suspension properties, stabilize emulsions, and improve stability to shear, heat, pH, or stability to freeze/thaw cycles. They can also promote penetration, lubricity, and slip and modify the ultimate skinfeel of the finished product. Overall, the addition of rheology modifiers contributes to emulsion stability and improves the shelf life of the product. The rheological additives that can be utilized to achieve these properties in various applications can be split into two categories: additives that can be used to modify water and additives that can be used to modify liquids other than water. Though this basic classification system can be useful, it should be remembered that many cosmetic systems contain both water and oil phases and can therefore use rheological additives from either group, depending on the need.

There are many rheological additives a formulator may select to obtain the desired properties of the final formulation. Often several rheological additives would perform well in a particular formulation and the formulator must make some choices. Considerations regarding the product application, labeling, consumer targets, and pricing come into play. However, more important considerations are the requirements of processing and the stresses the formulation will encounter. Therefore, the pH of the formulation, the processing temperature, shear circumstances, the packaging conditions, and the consumer's handling of the product are extremely important. The formulator must also consider the desired appearance and properties of the final formulation.

4.2.1.3 RHEOLOGICAL ADDITIVES USED TO OBTAIN SPECIFIC PROPERTIES

Using a rheological additive to create higher viscosity can greatly contribute to the emulsion stability of the finished formulation and therefore produce a longer product shelf life. These thickeners may be naturally or synthetically derived, organic or inorganic polymers. The effects of product viscosity changing due to changes in pH, temperature, or shear can be stabilized by using the right rheological additive. Thickeners also help to suspend active ingredients or pigments in formulations, such as using carbomers in lotions or organoclays in nail polish. Higher viscosity in formulas, especially skin and hair care products, is often associated with luxuriousness and therefore improved consumer acceptance.

Surfactant systems, such as shampoos, body washes, and shower gels can be very difficult to thicken and stabilize. Typical rheological additives used for these surfactant systems include carbomer, gums, gum derivatives, starch derivatives, aluminum/magnesium hydroxide stearate, hydroxypropylmethylcellulose, or simply salt.

Thixotropic rheology modifiers create viscosity in the formulation; however, when the formulation is applied to the skin or hair, it becomes thin so it can be evenly spread. In other words, these additives can cause the product's viscosity to decrease when the shear rate is increased. They do not immediately return to their original viscosity when the shear is removed, but the original viscosity will be recovered if given enough time. Therefore, formulators must consider the level of shear to which the formula will be subjected in the laboratory or in the manufacturing environment.

If the rheological additive in the formula is shear-sensitive, such as with large polymers or silicas, then the overall product rheology can be affected. The product structure may break down and the final product will no longer have the intended rheology. On the other hand, rheological modifiers like clays and organoclays and

some gums, like carrageenan, thrive on shear and will not break down under these conditions. The viscosity may even build higher with these shear-loving additives.

It is important to be aware of time and temperature when working with thixotropic rheology modifiers. The cooling rate of the product can affect viscosity and structure formation. If one tries to measure the viscosity of a thixotropic material without control of the length of time before testing, one may get results that are not reproducible since the time on the viscosity recovery curve is not controlled. The formulator must also keep these sensitivities in mind when testing and reporting accelerated stability results for products with thixotropic ingredients.

Pseudoplastic rheology modifiers are shear thinning when the shear rate is increased; however, they return to their original viscosity when the shear is removed. Good examples of pseudoplastic rheology modifiers are gums, like xanthan or guar gum. Carbomers, cellulosics, clays, and silicas also exhibit excellent pseudoplastic properties. The rheological additive is often chosen to achieve the desired product attribute when used by the end consumer. For example, a hand lotion may be formulated to rub in quickly, whereas a massage lotion or barrier cream will be formulated to have more play time and rub in slowly.

Rheological additives can increase the resistance to flow or yield value. It is important to have even distribution of the active ingredients, colors, and other additives in the formulation emulsion or suspension. Increasing the yield value can contribute to this stability. Flow properties can make or break consumer acceptance of products like lotions or shampoos. If the desired amount of product is not easily pumped or squeezed out of the package, the product itself may be wonderful, but the consumer may fail to purchase it again. Products like nail polish require good flow properties from their rheological additives to evenly distribute the wet polish on the nail; however, the brush marks must then disappear on the dry polished nail.

Emulsion technology is another key area for the use of rheological additives. Stabilizing emulsions against phase separation can be accomplished with two different rheological approaches: adding a rheological additive to the external phase or adding it to the internal phase. The first approach is the one most frequently used. By choosing an additive that either increases the viscosity of the external phase or introduces a yield value to that phase, the formulator can slow down the flow of the internal phase through the external one. Formulators can also adjust the rheology of the emulsion by incorporating a rheological additive into the internal phase. The stabilizing effect here is caused by making the internal phase more "deformation resistant." Using an oil-in-water emulsion as an example, a viscosity-increasing additive in the oil phase will make the oil droplets more resistant to deformation as they flow past each other. The harder they are to deform, the harder it will be for the oil phase to flow through the aqueous phase, thereby increasing the time required for creaming, phase separation, or coalescence.

Finished product stability is often a result of ensuring emulsion stability of the formula. Rheological modifiers are key ingredients in providing emulsion stability to formulations such as lotions, sunscreens, or cleansing products. As described above, these ingredients can be added to the internal or external phase, but are most often added to the external phase. They prevent phase separation often by building the viscosity of the product and slowing down the potential flow of one phase through the other.

There are many rheological additives that can be used to stabilize emulsions and often more than one is used in a formula. These additives not only thicken and suspend to stabilize the emulsions, but go beyond that to actually develop a polymer network that keeps the oil droplets from coalescing. Typical rheological modifiers used to stabilize formulas include natural gums and natural gum derivatives, cellulosic derivatives, starch derivatives, clays, fatty alcohols, synthetic polymers, or silicas. For example, synthetic polymers are often used for emulsion stability in creams and lotions or personal cleansing products. In aqueous systems, starch derivatives inhibit syneresis, which is the separation of water from the formulation. Controlling this moisture migration extends the shelf life of the product by maintaining a stable emulsion.

Insoluble additives are increasingly added to personal care formulations. These additives are often very fine in particle size and have a tendency to settle out of the formulation over time. Rheological modifiers are used to suspend these particles and create a stable product. Suspending agents are rheological additives since they change the rheology of the fluid, making it more difficult for the solid particles to flow through. Many suspending agents form a loosely bound structure within the liquid, and the solids become trapped and are supported in the formula. If the weight of the solid exceeds the strength of the supporting structure, the solid will settle. Therefore, fine particles suspend more easily than very large particles. Antiperspirants, sunscreens, liquid makeups, mascara, and nail polishes all depend on suspending agents to help distribution of active ingredients and pigments. Lipsticks also benefit from suspending agents. When a lipstick is manufactured, it is held in a molten state until it is poured into molds. When melted, it is critical that the pigments stay in uniform suspension; otherwise, some lipsticks of the batch may contain more pigment or color than others. After injecting the hot lipstick mass into a mold, it is also important that the pigment does not settle into the tip of the stick, or the lipstick's appearance will suffer. Examples of rheological additives that act as suspending agents include natural gums and natural gum derivatives, cellulosics, synthetic polymers, carbomer, starch derivatives, clays, silicas, polyethylenes, castor oil derivatives, and organoclays.

Rheological additives that are good film formers can enhance and stabilize foam in formulations such as shampoos, shaving creams, or body washes. A

product that produces more foam or lather does not necessarily mean the product is working better; however, many consumers believe this to be true. Consumers want good foam properties and for most, it is an indication that the product is cleaning the skin or hair better. While surfactants create the foam, rheological additives aid in the foam's properties and stability. Natural gums and natural gum derivatives, cellulosic derivatives, starch derivatives, fatty alcohols, and polyquaterniums help provide lather and stabilize foam, which improves consumer acceptance of the commercial product.

The film-forming properties in products like styling formulas, sunscreens, and shaving products are often attributed to the rheological modifiers used in the formula. For example, in sunscreens these additives help to distribute the active ingredients to protect the skin from the sun's rays and may even improve water resistance.

The lubricity of a formula can easily be modified by the addition of rheological polymers. When a cream or lotion is rubbed onto the skin, the amount of friction created can greatly influence the consumer's sensory perception of the product. Lotions, shaving products, shampoos, soaps, body washes, lipsticks, and sunscreens all benefit by improved lubricity. Natural gums and gum derivatives, starch derivatives, polyethylene glycols, castor oil derivatives, and stearic acid derivatives all impart lubricity to creams and lotions, cleansing products, and more.

Both nonionic and cationic rheological modifiers are added to formulations to improve the conditioning properties of the product. In shampoos, conditioners, and styling gels, cationic polymers help to smooth and control the hair. Polyquaterniums, cellulosics, starch derivatives, polyethylene glycols, and carbomers are good examples of rheology modifiers that provide conditioning properties.

Before a formulator selects the rheology modifiers to incorporate into the formula, they must determine the desired product appearance of the finished lotion, gel, suspension, or solid. Typical questions might be: Is the target a clear or opaque product? Would gloss inhibit or benefit the consumer perception of the product? Once these decisions have been made, an appropriate rheological additive can be selected. For example, if a clear formula is desired, a synthetic polymer, carbomer, or polyethylene could be tested. On the other hand, if the desired outcome is an opaque formula, clays or organoclays may be selected. Starch derivatives or gums could impart glossiness to the formula, if that is the objective.

Another choice a formulator must make is how the product will be administered from the container. Will it be pumped, poured, squeezed, etc? As discussed, the flow properties of a formulation are greatly affected by the choice in rheological additives incorporated into the formula. If a short texture (not stringy or slimy) is desired, a starch derivative in a lotion or silica in toothpaste is a good choice.

Another example is using polyethylene glycols, which come in a wide range of molecular weights, to adjust the desired formulation structure by increasing or decreasing molecular weight. Gums, gum derivatives, and highly substituted cellulosics can provide a long texture to formulas, if that is the aspiration.

Short-chain, low-molecular-weight polymers with low viscosity (thickening) properties are excellent rheological modifiers to improve the luxury and body of the formulas without drastically increasing the viscosity of the overall system. An example is using maltodextrin in a massage lotion where the formulator wants to increase the play time or time to rub the lotion into the skin.

4.2.1.4 RHEOLOGICAL ADDITIVES FOR AQUEOUS SYSTEMS

The category of rheological additives for water-based systems includes a number of natural and synthetic ingredients including gums and gum derivatives, cellulosic and starch derivatives, clays, polyethylene glycols, fatty alcohols, and polymers.

While there is an increasing consumer interest for natural formulations and the use of natural ingredients, the definition of "natural" is often debated. Also, the desire to formulate green formulations that are safe and mild, yet still effective, is a challenge to formulators. Historically, natural gums were often used for rheology modification; however, they have fallen out of favor with formulators due to their innate variability and availability. Because they are agricultural products, these natural polymers can vary depending on the year, climate, yield, etc. They also introduce the potential for microbiological contamination to the formulation. On the positive side, natural gums can provide a stable viscosity at a wide pH range and greatly improve product stability. They can also provide the formulation with salt tolerance. They can exhibit pseudoplastic or thixotropic rheological properties and are added into the water phase of an emulsion. Some gums can be pituitous (stringy or slimy), which can cause problems for rheological flow from containers, especially those with small pumping orifices where they can pull back into the container upon pumping. Examples of natural gums include carrageenan, xanthan, guar, tragacanth, locust bean, karaya, and alginates. Synergistic effects can be achieved by the combination of some of the natural gums with clay products, such as the use of xanthan or guar gum with aluminum magnesium silicate.

Hydroxypropyl guar is a good example of a nonionic, natural gum derivative with pseudoplastic properties. It develops high viscosity in a short amount of time, so it is a very versatile thickener. This rheological modifier is often used in lotions, shaving products, and shampoos not only for viscosity, but for its ability to impart lubricity. These derivatives are also compatible with alcohols, electrolytes, and surfactants, which make them even more functional in personal care formulations.

Cellulose is another naturally occurring polysaccharide, and through chemical modifications it accounts for a family of rheological additives that includes cellulose gum, hydroxyethylcellulose, methylcellulose, and hydroxypropylcellulose. Due to the modifications, some of the derivatives display excellent salt tolerance, surfactant compatibility, or film-forming properties, which make them particularly useful in certain shaving products, shampoos, and other hair care products. They can impart suspension properties to mascara, liquid makeup, and other pigmented products.

While cellulose gum provides thixotropic rheology, hydroxypropylcellulose, and hydroxyethylcellulose are good examples of pseudoplastic rheology modifiers that are thickeners and emulsion stabilizers. These rheology modifiers provide a stable viscosity in hair conditioners where many thickeners are not compatible with the cationic polymers. In addition, their film-forming properties enhance hair care products such as styling gels. Cellulosic derivatives may be hydrophobically modified to increase the surface activity of the rheological modifier.

When added to the aqueous phase of the formulation, starch-based derivatives help build viscosity, stabilize emulsions, suspend other ingredients, and improve film-forming properties of the formulation. With certain modifications, starch derivatives can prevent syneresis or the movement of water out of the emulsion. This extends the product shelf life and improves consumer acceptance. Starch derivatives can be stable to a wide range of pH, shear, and temperature. They also provide emulsion stability to freezing and thawing conditions. These polymers provide short-textured, thixotropic viscosity to a wide variety of formulations including creams, lotions, body washes, shaving creams, shampoos, and other aqueous emulsions. Because they are good film formers, starch derivatives improve foam properties in personal wash products, shampoos, and shaving products. They can also form freestanding films to use as a delivery vehicle for other ingredients. Some starch derivatives are emulsifiers and can be used to encapsulate active ingredients or fragrances, while others are designed to improve conditioning or flow properties.

Maltodextrins are low-molecular-weight glucose polymers derived from starch. They are used to improve the body or luxuriousness of creams and lotions, shaving products, and cleansing products. Since they are low molecular weight, they improve play time of a formula without greatly increasing the viscosity. They are very water soluble and often used in soap and cleansers, bath products, and pouched powder products to increase dispersibility of the formulations. They also impart humectant properties.

Clays can exhibit pseudoplastic rheological properties in water-based systems, but can also be highly thixotropic depending on the type of clay and formulation used. They are used primarily for viscosity enhancement, flow control, suspension,

and emulsion stability. There are different types of clays, and the different natural formations of these clays along with the different chemistries account for the various properties they provide. Clays may include bentonites, hectorites, synthetic hectorites, and magnesium aluminum silicates. Bentonites are based on aluminum silicates, while hectorites are based on magnesium silicates. Clays are very often used in combination with other thickeners, especially organic ingredients like cellulosics or gums. Clays tend to form opaque or tinted dispersions that must be considered when developing formulations. Hectorite is normally lighter in color than bentonites. These rheological modifiers are generally used in shampoos, lotions, and liquid makeups.

Polyethylene glycols (PEGs) are available in a range of molecular-weight polymers of ethylene oxide. These materials are soluble not only in aqueous systems but also in nonaqueous systems such as alcohols and glycols. They are widely compatible and unaffected by electrolytes. They are used as thickeners, humectants, and lubricants in creams and lotions, and as co-gelling aids for antiperspirant sticks. They exhibit high viscosity to form a matrix that suspends fine particles of active ingredients or pigments; however, when pressure or shear is applied they can easily break down to release the particles. The higher the molecular weight, the more effective the polymer is in providing viscosity. Polyethylene glycols below a molecular weight of 700 are liquid at room temperature. The PEGs can be used to create a particular melting point for personal care sticks and pastes. They can also help solubilize other ingredients like bath oils in body wash products.

Fatty alcohols, such as cetearyl alcohol, a blend of cetyl and stearyl alcohol, are widely used as rheological additives in lotions, creams, and hair care products. They not only create viscosity, but can also act as an emulsifier, emollient, opacifier, and foam booster. These ingredients are used in both aqueous and nonaqueous formulations and help to stabilize both water-in-oil emulsions and oil-in-water emulsions. They can be used to change rheology dependent on processing time and temperature.

Synthetic polymers contribute high viscosity and are used to thicken, suspend, and stabilize formulations. These polymers are used extensively in cosmetics formulations and are a polymer of choice for clear formulas. The main base used for most synthetic polymers is acrylic acid, and the polymer is described as a homopolymer (made entirely of one kind of polymer), copolymer (combinations of more than one type of polymer), or crosspolymer (copolymers with a cross-linking agent). These materials are supplied in a tightly coiled acid form and become effective only when uncoiled by neutralization with a base. These polymers create viscosity by swelling; they do not dissolve in water. Their effectiveness comes from both long-chain entanglement and hydrogen bonding; they are typically used at very low concentrations ranging from 0.1% to 0.5%. Most synthetic polymers

are limited by salt sensitivity, pH sensitivity, and the inability to withstand high levels of shear. Many synthetic polymers are also sensitive to UV light, and the formulation viscosity can be lost if exposed for periods of time. This is a concern for sun-care lotions and similar products.

Acrylic acid polymers, or **carbomers** are added to the aqueous phase and build pseudoplastic viscosity, create clear gels, and stabilize emulsions. They are often the main rheological additive in creams and lotions, body washes, shampoos, and hair-styling products for providing viscosity and film forming. Carbomers are used in lotions not only to create viscosity in the finished product, but also to allow the product to break down when applied to the skin due to their sensitivity to salt, thus allowing the lotion to rub in quickly. Synthetic cationic polymers are compatible with both cationic and nonionic surfactants and are used to thicken, suspend, and condition formulations such as hair care products.

Polyquaternium products are typically cationic polymers where the base polymer may be a cellulosic, synthetic, or other polymer. Because of the positive charge, these polyquaterniums are good conditioners and are widely used in hair care products. They are film formers, so they work well in hair-styling and conditioning products that contain cationic additives. They can bond with the hair or skin and form a protective film to prevent reaction to harsh surfactants or chemical treatments. They can improve slip and prevent moisture loss, thereby providing humectant properties. Some polyquaterniums are nonionic and also provide film-forming and stabilizing properties to cleansing, conditioning, and styling products.

In surfactant systems such as body washes, shampoos, or hand soaps, a common viscosity modifier is simply salt, sodium chloride. Especially when used with anionic surfactants, increasing the salt content of the formulation will increase the viscosity; however, a point is reached where adding additional salt will then decrease the viscosity. Formulators will typically create a salt curve measuring the viscosity of the product as the salt level is increased. The viscosity of the formula will increase to a peak and then as more salt is added, the viscosity will quickly decrease. The concentration of salt selected for the formula is typically the concentration just before the peak of the curve.

4.2.1.5 RHEOLOGICAL ADDITIVES FOR NONAQUEOUS SYSTEMS

Rheological additives for nonaqueous systems include silicas, polyethylenes, fatty acids, castor oil derivatives, aluminum magnesium hydroxide stearate, stearic acid derivatives, and organoclay pre-dispersions. The functional properties and potential applications for these additives cover a wide range of topics and products.

Silicas, or **silicon dioxides**, are used for building viscosity, for creating thixotropy, and for providing suspension properties. They build their thixotropic

structures in oil systems through a network of long chains and hydrogen bonds. These very fine particulates can be either porous or not, depending on their manufacturing process. The liquid process (hydrated silicas) yields a very porous material that can absorb oils, while the vapor or "fumed" process yields a higher surface area and a significantly reduced bulk density. Precipitated silica, a form of hydrated silica, is manufactured in both porous and nonporous forms, giving a product range of oil-absorption and thickening properties. Hydrated silicas and fumed silicas can provide the formulation with pseudoplastic or thixotropic rheological properties. Silicas are used in powder and liquid formulations for hair and skin care. They build structure and viscosity in toothpaste formulas. In powder formulations, they act as anti-caking agents or carriers as well as improving flow properties. In liquid formulations, they contribute to emulsion and viscosity stability, moisture resistance, and provide suspending properties. Care must be taken to avoid high shear processing after the addition of silica, since it can destroy the hydrogen-bonded network. Silicas can also be used to modify aqueous formulations.

Polyethylenes and their variants are thixotropic rheological modifiers used primarily for their thickening and suspending properties in anhydrous systems such as lipsticks, antiperspirant sticks, and mascaras. They improve water resistance, form films, improve heat stability, and can form clear gels when quickly cooled, allowing the formation of a fine thixotropic crystal structure. To achieve good properties, polyethylenes need to be heated to 80°C or higher, depending on the grade of polyethylene used. Polyethylenes contribute to emulsion stability and film-forming properties, which makes them suitable for creams and lotions, sunscreens, and hair care products.

Fatty acids are typically added to the oil phase of an emulsion to provide viscosity and stability to the formulation. In cleansing products like shampoos and body washes, they act as foam stabilizers and suspending agents to entrap the dirt and wash it away. Fatty acids and fatty-acid derivatives can be derived from plant or animal sources. Soybean, coconut, and palm oils are often used to manufacture fatty acids and fatty-acid derivatives. These additives greatly improve lubricity of the formulation.

Castor oil derivatives are used to increase viscosity of anhydrous formulations like ointments, lotions, foundations, lipsticks, and mascaras. They can also contribute to the moisturizing effects of a formulation on the skin. A good example of a castor oil derivative is trihydroxystearin, a thixotropic rheology additive that provides a high degree of viscosity, stabilizes emulsions, improves water repellency, and helps with suspension of active ingredients or pigments. It is used with organoclays to control the flow and recovery time in mascaras. When using castor oil derivatives, heat and shear, under carefully controlled process conditions, are necessary for full rheological development.

Aluminum magnesium hydroxide stearate is a complex of aluminum magnesium hydroxide and stearic acid, which can form gels in a number of cosmetic oils. These gels tend to be colorless and stable over a broad range of temperature. This ingredient provides thixotropic viscosity and emulsion stability to formulations like creams and lotions, ointments, antiperspirants, eye makeup, and lipsticks. This rheological modifier can suspend pigments and active ingredients and can increase the temperature stability of the formula.

Stearic acid derivatives are often used in cleansing formulations for viscosity and foam stabilization. They contribute a moisturizing effect to many formulas. Besides the thickening effects, these additives can contribute to the emulsion stability and emollient properties, improving the skinfeel of creams and lotions. Stearic acid esters impart a pearlescent appearance to shampoos and body washes.

Highly thixotropic rheology modifiers, organoclays are reaction products of hydrophilic clays with long-chain quaternary compounds, for example, quaternium-18 hectorite. The quaternary ammonium compound provides compatibility with nonaqueous liquids, allowing the primary clay rheology to be expressed in nonaqueous systems such as oils, esters, and silicones through a hydrogen-bonding structure between platelets. The organoclays are the rheological additives of choice in nail polish, makeups, hair gels, antiperspirant roll-ons, aerosols, and waterproof mascaras, due to their thickening and suspending abilities. To be fully dispersed, organoclay powders need chemical activation and very high shear; therefore, they are often available as pre-dispersions, where the organoclays are in fully activated and sheared forms in a number of cosmetic oils. Organoclay gels are unaffected by high-temperature or high-shear processing, though laminar flow can reduce the viscosity of the overall system. These rheological additives are added to the oil phase of the formulation and are often the first choice to thicken oil-based systems.

Some rheology modifiers typically used in nonaqueous systems may also be used in aqueous systems depending on the formulation. For example, synthetic polymers and polyethylene glycols can be used to modify either type of system.

New, very specialized rheology modifiers are being developed with specific goals in mind. Many are vegetable derived to target the growing natural market. Some of these polymers provide viscosity, water repellency, and improved product appearance as well as stability. It is in the formulator's best interest to educate themselves on new ingredients.

The formulator has many choices in determining the rheological additive that is right for their particular formulation. The decision must be based on the type of rheology required in the finished product. However, the formulator must be cognizant of compatibility with other formulation ingredients, the pH of the formula, the processing conditions, the need for clarity, and the desired consumer reception.

As in many cases, the final answer can be reached by several different paths. The formulator must consider the rheological additives available and weigh the advantages and drawbacks of each one. By continuing to learn and experiment with new rheological additives, new and unique formulas can be developed.

GLOSSARY

Acrylic acid polymers: High-molecular-weight rheology modifiers produced from acrylic acid and used as thickeners, emulsion stabilizers, and to create clear gels.

Aluminum magnesium hydroxide stearate: A complex of aluminum magnesium hydroxide and stearic acid used to form colorless gels in oil.

Carbomer: Polymers of acrylic acid used as thickeners, emulsion stabilizers and to create clear gels.

Castor oil derivatives: Rheology modifiers used to increase viscosity of anhydrous formulations.

Cellulose-Based Polymers: Naturally occurring polysaccharides usually chemically modified to create versatile rheological modifiers.

Clays: Naturally occurring minerals used for increasing viscosity, improving suspension properties, and controlling flow.

Conditioning: Improving surface properties by moisturizing, changing surface chemistry, or adding lubricity.

Emulsion: A mixture of oil and water where one phase is suspended as tiny droplets in the other phase to create a stable dispersion.

Fatty acids: Rheological additives based on natural acids, which create viscosity, lubricity, and improve stability of formulations.

Fatty alcohols: High-molecular-weight alcohols used as thickeners, opacifiers, and foam boosters.

Film formers: Ingredients capable of forming a film or continuous sheet on a surface or as a bubble.

Flow: The deformation or movement of a fluid.

Hydroxypropyl guar: Nonionic, natural gum derivative used to create viscosity, impart lubricity, and improve stability in formulations.

Lubricity: The reduction in friction when two surfaces are rubbed together.

Maltodextrin: Low-molecular-weight saccharide polymers derived from agricultural starch products and used to impart solids, lubricity, and suspension to formulations.

Natural gums: Polysaccharide polymers based on agricultural products and used as thickeners and rheology modifiers.

Organoclays: Reaction products of hydrophilic clays with long-chain quaternary compounds used as rheology modifiers in nonaqueous systems.

Polyethylene glycols: Polymers of ethylene oxide available in a wide range of molecular weights and used as rheology modifiers in formulations.

Polyethylenes: Rheological modifiers used as thickeners and suspending agents in anhydrous systems.

Polyquaternium polymers: Cationic polymers, based on cellulosic, synthetic, or other polymers, creating conditioning and film-forming properties.

Pseudoplastic: Shear thinning with immediate recovery when the shear is removed.

Rheological additives: Ingredients that modify flow characteristics of a fluid and add other functional properties to a formulation.

Salt: Common salt is sodium chloride, which is used for increasing viscosity in surfactant systems.

Sodium chloride: Common salt used to increase viscosity in surfactant systems.

Silica: A chemical compound, also known as silicon dioxide, used for building viscosity, structure, and suspension properties in formulations.

Silicon dioxide: A chemical compound, also known as silica, used for building viscosity, structure, and suspension properties in formulations.

Starch derivatives: Naturally derived polymers based on agricultural products usually chemically modified to create versatile rheological modifiers.

Stearic acid derivatives: Rheology modifiers used for viscosity, foam stabilization, and emollient properties.

Syneresis: The separation of water from a gel.

Synthetic polymers: Polymers, not derived from natural ingredients, used as thickeners and suspending agents in formulations.

Suspending agents: Ingredients that support the dispersion of solid particles in a liquid, making it difficult for the particles to flow through the liquid and settle out.

Thickener: Ingredient with the ability to create viscosity in a formulation.

Thixotropic: Shear thinning with a delayed recovery when the shear is removed.

Viscosity: A measure of the resistance of a fluid to deformation or flow. Thickness.

Yield value: The stress required to initiate flow or movement of a fluid.

ABSTRACT

All consumer product formulations have an inherent rheological character that is dictated by the raw materials used and how they are combined in the formulation. The rheological character is a description of the flow behavior over a range of shear rates and with the passage of time while being sheared. There are many parameters that contribute to the overall rheological character of a formulation. Viscosity is the most common rheological parameter encountered in formulation. Said simply, viscosity is the measure of flow of the fluid, over a range of shear rates from very low (like sitting in a container, or being poured) to very high (like being applied to the skin upon rubbing). Sometimes the viscosity is constant over the range of shear rates and with the passage of time. At other times, the viscosity may increase or decrease with shear and with the passage of time. Yield stress is a critical rheological parameter for imparting stability to emulsion formulations and to optical effects formulations, such as cleansers or hydroalcoholic formulations that have some type of optical effect, such as beads or air bubbles. Viscoelasticity is a third rheological parameter. Viscoelasticity is the balance of the viscous and elastic components of a material. It impacts the formulations visual aesthetic when it is at rest and the pick-up and cushion of formulations during rub-in. The array

of formulation attributes that are affected by its rheological character makes the design of the rheological behavior of a formulated product a crucial step in order to make a product behave in the desired way in the consumer's hands and during use.

4.2.2.1 INTRODUCTION

In this chapter we describe some of the key rheological modifier polymers, their structure in general, and the variables of structure that can be built in in order to provide a range of behavior in cosmetic and personal care formulations.

In many formulations, the rheological properties provided by the primary functional materials can provide the desired physical behavior and flow properties for the formulation. For example, an emulsion may be stable and sufficiently thickened only by the inclusion of emulsifiers and oils, and this resulting formulation will have its own unique rheological profile. Often, however, the primary functional materials of a formulation, such as emulsifiers and oils, are not sufficient to impart long-term stability, thickening, and a desirable rheology. In this case, polymeric rheology modifiers are typically employed. Polymeric rheology modifiers have the ability to impact multiple aspects of formulations, including formulation stability and the product's full sensory profile. The typical rheological parameters that impact personal care formulations are viscosity, yield stress, and viscoelasticity. It is critical to choose a polymeric rheology modifier that can help to deliver the desired product aesthetics to your formulation. The most commonly used synthetic polymeric rheology modifiers are modified sulfonic acid–based polymers, polyacrylic acid–based polymers, and alkali swellable emulsion–type polymers.

4.2.2.2 RHEOLOGICAL PARAMETERS

a. Viscosity

A primary function of polymeric rheology modifiers is to provide increased viscosity of the solvent, such as water. Viscosity is a measure of the resistance to flow when a shear stress is applied. For ideal viscous fluids, the value of the ratio of the shear stress, τ, to the corresponding shear rate, $\dot{\gamma}$, is a material constant called the apparent viscosity, η. These kinds of fluids are often referred to as Newtonian fluids. One example of such a fluid is polydimethyl siloxane. Many types of fluids in personal care exhibit a *pseudoplastic* or shear-thinning behavior with the applied force. In these fluids, the value of the ratio of the shear stress to shear rate decreases with the shear rate. Equations 1 and 2 and Figure 5 illustrate these behaviors:

$$\eta = \frac{\delta}{\gamma}\text{; h is constant, Ideal of Newtonian Fluid} \quad (1)$$

$$\eta(\dot{\gamma}) = \frac{\delta}{\gamma}\text{; } \eta \text{ varies with the shear rate, e.g., shear-thinning fluids} \quad (2)$$

With rare exceptions, Newtonian and pseudoplastic fluids are the two most common fluid types encountered in personal care formulations at room temperature and under typical conditions of usage. Note, however, that a large variety of rheological behavior, such as plastic, pseudoplastic, dilatant, rheopectic, thixotropic, is found in many other industrial fluids and formulations and has been extensively documented in the literature (1).

Graphical examples are best suited for illustrating rheological behavior, although there are numerous mathematical models that are used to describe such behavior (2) (3). Two types of graphs are commonly used. One is a plot of apparent viscosity versus shear rate as shown in Figure 1:

Figure 1. Typical graphical representation of viscosity versus shear rate for aqueous personal care formulated products.

The other way to graphically describe the rheological properties of a liquid formulation is to plot the shear stress versus shear rate data as shown in Figure 2. In this way data obtained at various temperatures and at varying concentrations of the rheology modifier and other formulation ingredients can be obtained and studied to fully characterize the rheological properties.

Figure 2. Typical graphical representation of shear stress versus shear rate for aqueous personal care formulated products.

A number of aqueous formulations in personal and home care obey the rheological flow behavior described in Figures 4 and 5. These include shampoos, bath gels, body washes, liquid soaps, hair gels, toothpastes, skin creams, lotions, pomades, etc. Many of these formulations are emulsions or contain dispersed solid matter such as beads, mica, pearlizing crystals, seeds, etc. However, from a

rheological viewpoint, the difference among these products is not essential; it is more of a quantitative than qualitative nature.

b. Viscosity Measurement

The viscosity of aqueous formulations in personal care is typically measured using various types of rotational and oscillatory rheometers. Rotational rheometers typically measure the torque on a probe such as a rotating plate, cylinder, or a spindle of certain specific geometry, in contact or immersed in the test fluid. The measured torque is correlated to viscosity by the instrument's processor. Typical measuring systems of the rotational type include a) concentric cylinders, b) cone-and-plate, c) parallel-plate and d) relative measuring systems. Brookfield rotational viscometers are relative measuring systems (4). They are extensively used to measure the viscosity of aqueous compositions of various kinds. They are inexpensive and simple to use; however, they only measure relative viscosity values or instrument-dependent values since the viscosity is measured with a specific spindle with no information of shear rate, which is required according to Newton's Law in equation 1. Oscillatory rheometers are instruments in which the probe instead of rotating is oscillating according to a periodic oscillatory motion, such as for instance a sinusoidal motion of either constant amplitude or frequency. The rheological information obtained includes a number of parameters that assess the viscous and elastic components of the formulation in terms of the elastic or storage modulus (G'), the viscous or loss modulus (G") and the loss factor (tan δ). One of the main advantages of this system is that the strain or deformation imposed on the fluid is very small. Regardless of the instrument used, temperature control is essential to perform accurate measurements, particularly in the case of aqueous formulations whose viscosity can significantly vary with a change of only ±1°C.

c. Viscosity of polymeric rheology modifiers

In order to understand the different thickening mechanisms of polymeric rheology modifiers it is necessary to review the basics of viscosity in relation to polymer solutions. When a fluid is at rest, solvent molecules move rapidly under Brownian motion. When a fluid is flowing, solvent molecules move rapidly in the direction of flow. A low viscosity fluid is obtained when the solvent molecules are undisturbed and able to flow rapidly. When solvent molecules are disturbed and need to flow around or through an obstacle, they move along a longer path or more slowly, both of which decrease the rate of flow of the fluid. The resulting macroscopic behavior, in both cases, will be that of a high-viscosity fluid.

Polymers in solvent exhibit a hydrodynamic volume. The hydrodynamic volume is the effective volume of space that the polymer fills. The chemical composition of a polymer will dictate the nature and strength of the interactions between that

polymer and its solvent. In a good solvent, the polymer has strong interactions with the solvent and exists in a more expanded conformation. This expanded conformation takes up more effective space and therefore the hydrodynamic volume of the polymer is greater. Solvent molecules flowing around or through a polymer with a greater hydrodynamic volume will move more slowly and will result in a high-viscosity fluid. As the hydrodynamic volume of a polymer in solution increases, so does the viscosity. By contrast, in a poor solvent, the interaction of the polymer with the solvent is unfavorable, so the polymer interacts preferentially with itself. This results in a more collapsed conformation. This collapsed conformation takes up less effective space and therefore the hydrodynamic volume of the polymer is smaller, resulting in a lower viscosity. As a general rule, the greater the hydrodynamic volume of the polymer, the higher the viscosity of the fluid. Polymeric rheology modifiers impart thickening properties based on this principle of hydrodynamic volume.

d. Yield Stress

Another primary function of polymeric rheology modifiers in formulations is to provide a yield stress or yield point. A fluid with a yield point begins to flow only when the external forces acting on it are larger than a certain shear stress commonly known as yield stress, τ_o. Equation 3 is a mathematical model of one such fluid from the many that have been proposed in the literature (5), where $f(\eta, \gamma, \tau)$ may be a mathematical function of the viscosity, η, shear rate, γ, and shear stress, τ.

$$\tau = \tau_o + f(\eta, \gamma, \tau) \tag{3}$$

Yield stress is a critical parameter to providing stability in emulsions and suspensions. In practice, the yield stress of personal care formulations is used to estimate the suspending power of the rheology modifier and to predict the shelf life of a product. Yield stress can be measured or estimated in many ways. The procedure of choice to estimate yield stress must be validated for each formulation by conducting shelf life stability tests. In many instances the yield stress of a formulation can be estimated by linear extrapolation of the shear stress data to zero shear rate (6). For this, it is important to measure shear stress at the lowest shear rates possible under very well-controlled experimental conditions. The yield stress, τ_o, shown in Figure 5, was measured in a rotational viscometer and required shearing the fluid at very low shearing rates through the use of a very sensitive rheometer, under well-controlled experimental conditions.

Synthetic polymeric rheology modifiers may be linear or cross-linked polymers. Cross-linking of polymer molecules provides a network structure that imparts a particular yield stress to an aqueous formulation. The degree of cross-linking impacts the yield stress such that typically polymers with a higher degree of cross-linking exhibit higher yield stress.

e. Viscoelasticity

A third critical rheological parameter in the design of personal care formulations is the viscoelasticity. Viscoelasticity is the balance between the viscous and the elastic components of materials. Elastic materials deform when subjected to an applied force, and the deformation reverses completely and spontaneously when the applied force is removed. Viscous materials deform when subjected to an applied force, and the deformation stops when the applied force is removed. Most practical materials exhibit both viscous and elastic behavior and are referred to as viscoelastic. The balance of the viscous and the elastic components dictates the behavior of the material when a forced is applied (7).

Viscoelasticity can be measured with a rotational viscometer or a rheometer using an oscillatory technique. The relationship between the viscous component and the elastic component is described by the ratio, tan δ, of the storage or elastic modulus (G') and loss or viscous modulus (G"), Equation 4.

$$tan\ \delta = \frac{G''}{G'} \tag{4}$$

When *tan* δ < 1, the elastic modulus is dominant. When *tan* δ > 1, the viscous modulus is dominant. A model strain sweep of a viscoelastic material is shown in Figure 3.

Figure 3. Model strain sweep of a viscoelastic material. G' is the storage modulus and G" is the loss modulus.

4.2.2.3 SYNTHETIC POLYMERIC RHEOLOGY MODIFIERS

There are a variety of polymeric rheology modifiers available to the personal care industry, including both synthetic and natural polymers. Natural polymeric rheology modifiers derived from polysaccharides are discussed in more detail by

Laba (8). Synthetic rheology modifiers are produced by polymerization of various types of monomers. Among the synthetic polymers, those prepared by free radical–initiated polymerization of vinyl, acrylate, or methacrylate and acrylamide or methacrylamide monomers constitute an important class of commercially available materials (9, 10). Depending on the monomers used, these polymers may be anionically or cationically charged; the anionic polymers being the most common synthetic rheology modifiers. The anionic charge in these polymers is typically provided by carboxylic and sulfonic moieties existing along the backbone of the polymers. Furthermore, and for convenience, these polymers are classified based on the form they are supplied as powder, liquids, emulsions (oil in water), and invert (water in oil) emulsions. In this chapter we will review the most commonly used synthetic polymeric rheology modifiers in personal care formulation: modified sulfonic acid–based polymers, polyacrylic acid–based polymers, or alkali-swellable emulsion type polymers.

a. Modified Sulfonic Acid (AMPS®) Polymers

Polymeric rheology modifiers based on modified sulfonic acid chemistry are often referred to as AMPS® polymers. The chemical structure of AMPS® is acrylamido-2,2-dimethyl propane sulfonic acid, and the AMPS® monomer is present in all AMPS® polymers designed for rheology modification. Different co-monomer structures are combined with AMPS® to provide a range of polymeric rheology modifiers. All of these polymers are chemically cross-linked, which provides, in part, their thickening ability. The range of different co-monomers leads to polymers that have different effects on many attributes provided by the polymer in formulations. These include, for example, electrolyte compatibility, thickening effects, and skinfeel sensorics.

Ammonium acryloyldimethyltaurate/VP copolymer (Aristoflex® AVC)[19], Figure 4, is one of the most commonly used AMPS®-based polymeric rheology modifiers. The co-monomer in Aristoflex® AVC is vinylpyrrolidone (VP).

Figure 4. Ammonium acryloyldimethyltaurate/VP (Aristoflex® AVC) copolymer chemical structure.

Ammonium acryloyldimethyltaurate/beheneth-25 methacrylate crosspolymer (Aristoflex® HMB), Figure 5, is a hydrophobically modified polymeric rheology modifier, due to the beheneth-25 methacrylate co-monomer. The addition of

hydrophobic groups to the AMPS® polymer chain provides a rheology modifier with an increased affinity for hydrophobic formulation components, such as oils and silicones. These polymers act as thickeners due to the cross-linking present in all Aristoflex polymers as well as efficient polymeric emulsifiers that can stabilize high oil loads without the need for traditional emulsifiers.

Figure 5. Ammonium acryloyldimethyltaurate/beheneth-25 methacrylate crosspolymer (Aristoflex® HMB) chemical structure.

There are distinct rheological differences between Aristoflex AVC and Aristoflex HMB due to the differences between the vinylpyrrolidone and beheneth-25 methacrylate co-monomers used in polymerization. Within the class of AMPS® polymers, a wide range of final chemistries is available based on selected co-monomers for use with the AMPS® monomer. Variations in the co-monomer structure and the cross-linking of the polymer chains significantly affect the thickening and yield properties of AMPS®-based polymers.

b. AMPS® Polymers Rheological Properties

AMPS®-based polymers have a permanent negative charge due to the sulfonic acid moieties in the AMPS® co-monomer, independent of pH. These polymers have a high degree of cross-linking so that although the charged sulfonic acid moieties repel each other, a permanent network structure exists. The negatively charged sulfonic acid moieties interact strongly with polar solvents, such as water, and the solvent swells the network structure to produce a larger hydrodynamic volume and thus thickening of the solvent-based formulation. This interaction of solvent and polymer is presented schematically in Figure 6.

The co-monomer structure affects the strength of the polymer-solvent interactions as well as the degree of swelling of the network structure. Aristoflex polymers with higher charge density or more polar moieties will swell more quickly and reach a greater overall viscosity. As with all polymeric rheology modifiers,

an increased polymer molecular weight results in increased thickening at lower polymer concentrations. The viscosity profile varies depending on these properties as shown in Figure 7.

Figure 6. Swelling of network structure of AMPS®-based rheology modifiers.

Figure 7. Viscosity as a function of polymer concentration for AMPS®-based polymeric rheology modifiers Aristoflex® AVC and Aristoflex® Velvet, AMPS®-based terpolymer. Brookfield Viscometer Model RVDV-1, 20°C, 20rpm.

Aristoflex polymers with high degrees of cross-linking have a more elastic network, resulting in higher yield values and more elastic character. The *tan* δ as a function of polymer concentration for Aristoflex® HMB is shown in Figure 8 (11).

Figure 8. Elastic modulus, G', as a function of frequency for 0.5%, 0.7%, and 1.0% Aristoflex® HMB in DI water. Values of *tan* δ are at $1s^{-1}$.

The yield point of Aristoflex® HMB in DI water is 0.3% (11). At all Aristoflex HMB concentrations above the yield stress, *tan* δ < 1 indicates a dominant elastic component. An increase in the concentration of Aristoflex HMB provided an increase in the elastic component of the gel.

c. Polyacrylic Acid Polymers

An important class of anionic acrylate-based rheology modifiers is based on high-molecular-weight cross-linked polyacrylic acid technology. These polymers are commonly known by their INCI names carbomer and acrylates/C10-30 alkyl acrylate crosspolymer. They are used extensively in a variety of aqueous formulations including personal care, home care, pharmaceutical, and other industrial applications. Some examples are given on Table 1.

Table 1: Examples of Formulated Products with Carbomer and Acrylates/ C10-30 Alkyl Acrylate Crosspolymer

Body Care: Bath Gel, Body Wash, and Creams	Sun/After Sun: Tanning Lotions and Soothing Creams	Eye Color Cosmetics: Eye Shadow, Mascara
Face/Neck Care: Creams and Soaps	Foot Care Creams	Hair Conditioner
Shampoo	Hair Treatments: Hot Oils, Cold Waves, Straighteners	Lip Color Cosmetics: Lip Color, Lip Pencil, Rouge, Creams
Hand/Nail Care	Shower Products	Eye Color Cosmetics: Eye Lash, Eye Shadow, Eye Liner
Hair Styling: Gels and Pomades	Women's Fragrances	Shaving Preparations: Foam and Gel
Eye Care Creams	Face Color Cosmetics, Makeup	Women's and Men's Fragrances
Liquid Soap and Detergents	Foundations, Fluid Illuminators, Glitter	Bath Additives
Sun Care: Sunscreen Lotions, Creams and Spray	Face Color Cosmetics - Primers	Depilatory Products
Hair Colorants and Hair Dyes	Body Color Cosmetics	Eye Cleansers

The chemical structure of these polymers is shown in Figure 9.

A B

Figure 9. A) Chemical structure of carbomer and **B**) Acrylates/C10-30 alkyl acrylate crosspolymer, R = C_{10}-C_{30} Alkyl.

d. Polyacrylic Acid Polymers Rheological Properties

The viscosifying properties of polyacrylic acid polymers are strongly dependent on molecular weight, degree of cross-linking, the level of hydrophobic alkyl groups in their backbone, the pH and concentration in the formulation. Additionally, the charge character of acrylates-based polymers is typically imparted by the carboxylic acid functionality and is therefore dependent upon pH of the formulation. At low pH, below about pH 3.5, the carboxylic acid groups on the polymer are protonated and thus have no effective charge. This results in decreased polymer-solvent interactions, which provide a collapsed polymer conformation and low hydrodynamic volume. Thus, at pH less than about 3.5, acrylates-based polymers provide relatively low viscosity increase to water-based formulations. However, as the pH is increased above pH 3.5, neutralization occurs and the carboxylic acid group is deprotonated and exhibits a negative charge. Deprotonated carboxylic acid functionalities interact strongly with polar solvents, such as water. In addition, neighboring carboxylic acid moieties on the same polymer molecule repel each other due to charge interactions. This results in an increased hydrodynamic diameter and significant thickening of the formulation as illustrated in Figure 10.

Figure 10. Neutralization with a base creates negative charges along the backbone of the polymer. These repulsive forces uncoil the polymer into an extended, highly swollen structure.

In practice, and as result of this process, the viscosity of aqueous solutions of polyacrylic acid polymers exhibits a significant increase at pH of 3.5 to 5.0, reaching a maximum plateau at pH 5.5 to 10 and then decreasing at pH above 10 as shown in Figure 11 (12).

Figure 11. Neutralization scheme for polyacrylic acid–based rheology modifiers. Carbopol® Ultrez 10 and Carbopol® ETD 2050 polymers are cross-linked carbomers and Carbopol EDT 2020 is a cross-linked, hydrophobically modified carbomer.[20] All polymers at 0.5 wt%, neutralized with NaOH. Viscosity measured at 25°C with Brookfield viscometer Model RVT with spindle rotating at 20 rpm.

The degree of cross-linking of polymeric rheology modifiers is a critical parameter affecting the viscosification properties. Figures 10 and 11 show the viscosity values for aqueous solutions of carbomer polymers synthesized with relatively low degrees of cross-linking, Figure 12, and higher degrees of cross-linking, Figure 13, at various concentrations of the polymer. These data show that in general, the higher the degree of cross-linking of the polymer, the greater the viscosity it can provide to a formulation.

Figure 12. Relative viscosity of aqueous solutions of carbomer polymers with relatively low degree of cross-linking. pH ~ 7.5 adjusted with NaOH; viscosity measured at 25°C in a Brookfield RVT viscometer with spindle rotating at 20 rpm.

Figure 13. Relative viscosity of aqueous solutions of carbomer polymers with relatively high degree of cross-linking. pH ~ 7.5 adjusted with NaOH; viscosity measured at 25°C in a Brookfield RVT rheometer with spindle rotating at 20 rpm.

The degree of polymer cross-linking also affects the yield stress values. Figure 14 shows the Brookfield Yield Stress Values (6) for aqueous solutions of carbomer polymers synthesized with various degrees of cross-linking at various concentrations of the polymer. The equivalent degree of cross-linking for this set of carbomers increases in the following order:

CBP934 > CBP980 > CBP940 > Ultrez 10 > Ultrez 21 > ETD 2020> ETD 2050 > CBP941[21]

Typically, yield stress values increase with an increased degree of cross-linking of the polymer molecules. However, parameters such as polymer molecular weight also affect the yield stress. For example, CBP934 has the highest degree of cross-linking of the series evaluated, but the polymer molecular weight is low. The yield stress is less than that of polymers with lesser degrees of cross-linking due to the influence of the molecular weight.

Figure 14. Brookfield yield stress values for aqueous solutions of carbomer polymers with various degrees of cross-linking as a function of polymer concentration at pH 7.0. Yield stress values were measured using the Brookfield method at 25°C. All polymer solutions were neutralized with NaOH.

e. Alkali Swellable Emulsion Polymers - ASE/HASE Polymers

Alkali Swellable Emulsions (ASE) and Hydrophobically Modified Alkali Swellable Emulsions (HASE) polymers constitute a group of rheology modifiers widely used in the formulation of personal and home care products. These are also carboxy-functional polymers prepared by the free radical polymerization of

ethylenically unsaturated monomers. They are polymerized in aqueous emulsion (latex) of water-insoluble monomers that are emulsified in water by the use of suitable surfactants or suspending agents. A detailed account of the synthesis of these materials and properties as rheology modifiers was published by Jenkins (13, 14) and Shay (15). Liquid emulsion rheology modifiers are supplied as low-viscosity fluids that can be easily added and dispersed in aqueous formulations without the need of special mixing equipment or extended mixing times. Once incorporated into the formulation they are neutralized with base to allow them to swell and thicken the product. These polymers have been used extensively in a number of personal care products such as hair styling gels and pomades, shower products, shampoo, face/neck care, body care creams, liquid body soaps, hair colorants, hair treatments, shaving gels, liquid hand soap, etc.

As shown in Figure 15, the backbone of both alkali-swellable emulsion polymers (ASE) and hydrophobically modified alkali-swellable emulsion polymers (HASE) consist primarily of methacrylic acid and an assortment of acrylate or methacrylate alkyl ester monomers. In some cases relatively small amounts of other carboxylated monomers such as acrylic acid, fumaric, and itaconic acids are used. Additionally, HASE polymers typically contain 0–3 mol % of hydrophobic groups attached to the polymer backbone by means of a medium-length polyethylene oxide, hydrophilic segment, or spacer.

ASE

HASE

Figure 15. Chemical structure of alkali-swellable emulsion polymers where - m, n, and p represent the moles of monomeric (e.g., acrylic or methacrylic acid, alkyl (R) acrylate or methacrylate esters) units in the backbone of the polymer and q is the moles of the ethylene oxide spacer connecting R″ to the backbone. R″ may be a cetyl, stearyl, or behenyl fatty acid alkyl group, i.e., the associative group of the polymer. Y may be H of CH3.

f. Rheological Properties of ASE/HASE Polymers

Viscosification using alkali-swellable emulsion polymers (ASE) and hydrophobically modified alkali-swellable emulsion polymers (HASE) is dependent upon pH of the formulation. In aqueous solution and in their unneutralized state the polymer chains are hydrophobic; hence they exist in the form of coiled emulsion droplets. Upon neutralization of the carboxylic groups in the backbone of the polymers with a base such as sodium hydroxide, the emulsion droplets swell and the polymer coils expand, resulting in significant viscosity increase. This process is schematically illustrated in Figure 16.

Figure 16. Schematic representation of the polymer swelling process of ASE or HASE rheology modifier as a function of neutralization with base.

The viscosifying properties of ASE or HASE polymer rheology modifiers are strongly dependent on a number of factors including molecular weight, degree of cross-linking, the number of associative groups in the backbone, the pH and temperature of the solution, the concentration of thickener in the formulation, interaction with surfactants, oils, electrolyte, other ingredients in the formulation, etc.

The molecular structure of the polymers has a significant effect on the performance of the polymers as rheology modifiers. While the composition of the polymer backbone in ASE and HASE polymers may be for the most part equivalent, the addition of small quantities of an associative group in HASE-type polymers has a significant effect on the rheological properties of the polymer. Figure 17 compares the viscosity of an ASE polymer (Carbopol® Aqua SF-1, SF1 polymer; INCI name Acrylates Copolymer) with a HASE polymer (NovethixTM L-10 Copolymer, NL10; INCI name Acrylates/Beheneth-25 Methacrylate Copolymer)[22] under equivalent test conditions. The backbone composition of both rheology

modifiers is approximately equivalent. NL10, a HASE-type polymer, also includes small amounts of an associative thickener monomer; see Figure 17. As result, it can be easily seen that L10 exhibits large viscosity gains as the concentration of the polymer increases. Conversely the viscosity of SF1 exhibits a linear dependency with its concentration. The hyperbolic viscosity gains in NL10 are due to structuring via the associative groups, which tend to form stable physical intermolecular bridges.

Figure 17. Viscosity dependency of ASE (Carbopol® Aqua SF-1 polymer) and HASE (Novethix™ L-10 Copolymer) polymer mucilage in water vs. concentration. RVT Brookfield viscometer rotating at 20 rpm, 20°C, pH 7.0 to 7.5 adjusted with NaOH.

4.2.2.4 RHEOLOGICAL PROPERTIES AND THE CONSUMER EXPERIENCE

The rheological profile of personal care formulations should be a primary consideration in developing consumer-preferred products. The interactions of polymers in simple solvents as described previously, such as water, are well understood. However, in personal care formulations the interaction of polymeric rheology modifiers

with other ingredients adds a level of complexity and impacts their rheological behavior. Some considerations in these practical applications include interaction with charged species, such as emulsifiers, surfactants, or electrolytes, and combination with other functional ingredients, such as preservatives. It is also advantageous to accommodate specially required rheological profiles that connote claimed or desired consumer benefits.

Polymeric rheology modifiers have the ability to impact multiple flow behavior aspects of personal care products. Examples of these include: formulation stability, the appearance of the product, the application of the product, and the sensory feel of the product during and after use. Formulation stability is of primary importance to all formulators, and the rheology of the product contributes significantly to the stability, especially the yield stress imparted by the rheology modifier. Consumers experience a product in multiple stages during use, and all of these experiences lead them to their final decision on the product benefits. The sensory profile of a product is a tool that formulators use to help deliver the claimed benefits to the consumer, and the rheological character of a formulation influences many stages of the overall sensory experience. The appearance of the product at rest in the package is the first visual cue to the consumer of the benefit of the product. The viscosity and the viscoelasticity of the product are important during this initial experience. The application of a product to skin is an experience that can be controlled by the rheology of the product, in particular the shear behavior. The feel of the product on skin during use and after use are also impacted by the polymeric rheology modifier, particularly in the elasticity and shear behavior and also by the chemistry of the polymer molecule. Depending on the desired benefits and claims of the product, polymeric rheology modifiers can be chosen to help connote to the consumer the desired product benefits.

In the field of personal care there are many different types of formulations. Each of these has basic rheological needs, as outlined in Table 2.

Table 2: Basic rheological needs of personal care formulations

Formulation Type	Components					Rheological Needs
	Water	Solvent	Surfactant / Emulsifier	Oil	Poly-mer	
Gels	X	(X)			X	Viscosification; shear thinning
Optical effects cleansers	X		X		X	Low yield stress; pourable

Conventional O/W emulsions	X		X	X	X	Yield stress; shear thinning; viscoelasticity
Crème gels	X			X	X	Yield stress; shear thinning; viscoelasticity

The components of each type of formulation can offer unique challenges to developing a desirable rheological profile. The same polymer molecule can deliver a different rheological profile depending on the other components present in the formulation. In the following sections we will address these different formulation types in more detail.

4.2.2.5 POLYMERIC RHEOLOGY MODIFIERS IN EMULSION FORMULATIONS

Rheology modifiers are commonly employed in conventional emulsions and in crème gels. Conventional emulsions are formulated with amphiphilic emulsifiers to reduce interfacial tension between the oil droplets and water external phase (O/W emulsions) or water droplets and oil external phase (W/O emulsions). In conventional emulsions, polymeric rheology modifiers impart yield stress for stability, viscoelasticity for visual and feel aesthetics, and shear-thinning properties for application aesthetics. Crème gels are emulsions that do not contain traditional emulsifiers. The polymeric rheology modifier stabilizes the internal phase droplets in the external phase. It also imparts all of the yield stress, viscoelasticity, and shear-thinning properties as in a conventional emulsion.

a. Yield stress for emulsion stability

Polymeric rheology modifiers serve a primary function in emulsion formulations of providing enhanced stability in systems that are inherently thermodynamically unstable. Rheology modifiers provide suspension of emulsion droplets, which decreases the rate of instability due to coalescence or creaming. Suspension properties are imparted by yield stress and an increased yield stress will provide increased stability. The concentration of polymer employed to impart stability must be balanced to provide an adequate yield stress while maintaining a flowable liquid that can be utilized by a consumer.

Loeffler and Miller studied the yield stress as a function of Aristoflex® AVC concentration in both a conventional emulsion formulation and a crème gel formulation, Figure 18 (16).

Figure 18. Yield stress of Aristoflex® AVC as a function of concentration in crème gel and traditional emulsion formulations.

An initial yield stress was observed at 0.3% Aristoflex® AVC in the crème gel formulation. An initial yield stress was observed at 0.375% Aristoflex® AVC in the emulsion formulation. At all Aristoflex® AVC concentrations, the yield stress of the crème gel was significantly higher than that of the conventional emulsion. The interaction of the oil droplets with the polymeric rheology modifiers is different in the crème gel and the conventional emulsion due to the presence of traditional emulsifiers in the latter. Miller and Loeffler studied the yield stress as a function of Aristoflex® HMB concentration as shown in Figure 19 (17).

Figure 19. Yield stress of Aristoflex® HMB as a function of concentration in crème gel and traditional emulsion formulations, and aqueous gels.

A similar trend was observed, where the initial yield stress was observed at a lower Aristoflex® HMB concentration for the crème gel compared to the conventional emulsion, 0.275% and 0.3%, respectively. The yield stress of the crème gel was significantly greater than that of the conventional emulsion at all Aristoflex® HMB concentrations. It was also observed that the yield stress in both a crème gel and a conventional emulsion was significantly greater than in an aqueous gel. Thus, the presence of oils in the formulation increased the overall yield stress.

b. Relationship between rheological properties and the sensory experience

It is important to establish a correlation among the rheological properties of the emulsion with subjective properties that a skin care cream user would experience during rubbing of the emulsion over her skin. There are four primary sensoric properties that can be clearly related to the rheological parameters of an emulsion formulation:

- Speed of breakdown during rub-in
- Spreadability during rub-in
- Cushion
- Skin afterfeel once rub-in is complete

c. Speed of Breakdown

Speed of breakdown during rub-in is governed by the initial interactions between the polymer in the emulsion formulation and skin. The chemistry of synthetic rheology modifiers dictates their interaction with skin and moieties contained within skin, such as NaCl. Both AMPS®-based and polyacrylic acid rheology modifiers rely on their charge character and cross-linked network structure to provide thickening to a formulation. Upon exposure to NaCl, the repulsions between neighboring anionic charges are effectively screened, resulting in a viscosity decrease. Also, NaCl concentration gradients between the skin and the formulation cause a decrease in swelling of highly cross-linked networks in these polymers. Osmosis drives water diffusion out of the swollen polymer network and into the high-salt region of the skin, which results in a collapse of the polymer network. During rub-in, this decrease in viscosity is perceived by consumers as the breakdown of the formulation. A schematic representation of this collapse mechanism is shown in Figure 20 for AMPS®-based rheology modifiers. Variations in co-monomer structure, degree of cross-linking, and other parameters can influence the speed of breakdown during rub-in on skin.

Water hydrates and swells anionic polymer

Osmetic water diffusion due to salt on skin surface; polymer collapses

Figure 20. Collapse of network structure of AMPS®-based rheology modifiers upon contact with skin.

d. Spreadability

Spreadability during rub-in is the ease with which the product is spread over the skin and can be directly related to the shear response of the formulation. The response of an emulsion to shear can connote different product benefits to the consumer, though as a general rule, shear-thinning formulations are ideal for rubbing over the skin. The shear response for a crème gel, a conventional emulsion, and an aqueous gel containing 0.6% Aristoflex® HMB was evaluated by Miller and Loeffler, Figure 21 (17).

Figure 21. Shear-thinning behavior of 0.6% in crème gel and traditional emulsion formulations, and aqueous gels.

All formulation types exhibited shear-thinning behavior. The rate of shear thinning was similar for the crème gel and the conventional emulsion. The aqueous gel rate of shear thinning was similar up to 10 s^{-1}. The viscosity decrease as a function of shear rate was approximately linear for both the crème gel and the conventional emulsion. The crème gel viscosity was greater initially and this increase was maintained over all shear rates.

A conventional emulsion was evaluated for shear response as a function of rheology modifier chemistry. The composition of the emulsion is shown on Table 3. It is important to note that the amount rheology modifier that was added to the emulsion was adjusted to obtain viscosity between 28,000 and 33,000 mPa·s, measured at 25°C using an RVT Brookfield rheometer with spindle rotating at 20rpm. This narrow range of viscosity was selected as representative of the viscosity of a good skin cream.

The flow curves in Figure 22 show that there are practically no differences in the rheograms of the different emulsions throughout the entire shear-rate range. These data indicate that all of the emulsions containing Carbopol® polymers are shear thinning, which makes them ideal for rubbing over the skin.

Figure 22. Steady state flow curves for the emulsion in Table 3 thickened with different Carbopol® polymers. No electrolyte added.

Since the surface of the human skin contains electrolytes such as NaCl, determining the rheological behavior in the presence of NaCl is important. Figure 23 shows the flow curves for the same emulsions to which 0.05 wt% of NaCl was added. The addition of small amounts of electrolyte offers differentiated flow patterns.

Figure 23. Steady state flow curves for the emulsion in Table 3 thickened with different Carbopol® polymers and containing 0.05 wt% of NaCl.

Emulsions formulated with Ultrez 10, 20, and 21 have high electrolyte tolerance and exhibit relatively low viscosity drop in the presence of salt. As will be explained below, these polymers give emulsions having varying degrees of cushion and pick-up and in general they tend to feel less watery upon rubbing over the skin. On the other hand, emulsions formulated with CBP940 or CBP980 polymers are more sensitive to salt; the viscosity of the emulsion falls to relatively lower values in the presence of electrolyte. These emulsions tend to break down faster and feel light and more watery.

Table 3: Water in Oil Screening Emulsion

Part	Trade Name	INCI	% weight					
A	Carbopol® Ultrez 10 polymer	Carbomer	0.40					
	Carbopol® Ultrez 20 polymer	Acrylates C10-C30 Alkyl Acrylate Crosspolymer		0.75				
	Carbopol® Ultrez 21 polymer	Acrylates C10-C30 Alkyl Acrylate Crosspolymer			0.38			
	Carbopol® 940 polymer	Carbomer				0.30		
	Carbopol® 980 polymer	Carbomer					0.40	
	Carbopol® 934 polymer	Carbomer						0.50

e. Pick-Up and Cushion

Viscoelasticity is an important rheological parameter to evaluate when considering the "at rest" aesthetics, pick-up, and cushion of emulsions. Viscoelasticity relates to the "stability of shape" of the formula as well as the cushion during application. Stability of shape dictates how the formulation will appear at rest in the package. The viscous component of the formulation, G", relates to the flowability of the formulation. The elastic component of the formulation, G', relates to the stability of shape of the formulation. The relationship between the viscous component and the elastic component is represented by tan δ as discussed previously in Equation 4. Formulations with tan δ > 1 have a larger viscous component and are more flowable. Formulations with tan δ < 1 have a larger elastic component and have more stability of shape. The viscoelasticity of Aristoflex® AVC was evaluated by Loeffler and Miller (Figure 24) (16).

Figure 24. Frequency dependence of storage and loss moduli for emulsion with 1% Aristoflex® AVC.

The Aristoflex® AVC provides high elasticity in the formulation. This will result in a formulation that appears stiff and solid. The pick-up and cushion of an emulsion formulation are also related to the elastic component. High elastic component imparts poor pick-up, and it may be desirable to include formulation

components that lower the elastic component or increase the viscous component in order to improve the pick-up aesthetic of the formulation. Formulations with greater elasticity will have more cushion and may give the perception of a richer formulation. Formulations with a greater viscous component will have low cushion and may give the perception of lightness or freshness. A balance of the viscous and elastic components is critical to connote the desired benefits of a formulation to the consumer.

As with the shear-thinning behavior, the viscoelasticity of an emulsion containing a polymeric rheology modifier can be affected by the presence of NaCl. Dynamic or oscillatory rheological studies indicate that conventional emulsions present various degrees of elasticity and yield stress depending on the chemistry of the rheology modifier. Figure 25 shows the elastic modulus, G', for the emulsions on Table 3 with and without electrolyte added to the emulsion for different carbomer polymers.

Figure 25. Effect of electrolyte on the Elastic Modulus, G', and Yield Stress rheological properties of the skin care emulsion in Table 3, prepared with various carbomer polymers.

The elasticity of the emulsions decreases considerably in the presence of electrolyte. For instance, G' for the emulsion with Carbopol® 940 polymer decreases from about 600 Pa to about 150 Pa upon addition of 0.05% NaCl. This seems to indicate that the emulsion in contact with skin would turn rapidly much less elastic and possibly spread out much more easily. Conversely the elasticity of the emulsion prepared with Ultrez 20 polymer remains practically unaffected by the electrolyte. Interestingly, while the elastic modulus for most polymers is lower in the presence of electrolyte, the plateau region does not seem to be significantly affected and shows Yield Stress (inflexion region) within the same range.

f. Skin Afterfeel

As discussed in reference to the breakdown of polymeric rheology modifiers upon contact with skin, the chemistry of these polymers affects their interaction with skin, both on initial contact and after application. The skin surface has a chemical makeup that interacts with formulation ingredients through hydrogen bonding and hydrophobic associations. These skin–ingredient interactions and associations impart a skinfeel to each formulation. Thus the chemistry of the rheology modifier has an impact on the skinfeel during use and the skin afterfeel once the product is rubbed in. Molecules with large hydrophobic groups interact with the skin to give a substantive sensation. Consumers generally acknowledge these materials to have high moisturization or conditioning benefits. Synthetic polymeric rheology modifiers can be designed so that the comonomers contribute to the salt tolerance and the chemical interactions with skin in order to provide different sensory profiles to the consumer that connote a range of benefits from the formulation. For example, Aristoflex® AVC has a low salt tolerance and minimal chemical interactions with the skin due to the vinylpyrrolidone co-monomer. The resulting sensory profile is a rapid breakdown upon application to skin and a neutral feeling on the skin during and after application. Aristoflex® HMB has a higher salt tolerance. The hydrophobic beheneth-25 pendant chain interacts with the skin through hydrogen bonding, and the long carbon chain provides a substantive feeling to the skin. The resulting sensory profile is a slower breakdown and a moisturized feeling on the skin during and after application.

g. Correlation of Rheological Measurements and Consumer Perception in Emulsion Formulations

When developing new formulations to delight the consumer's senses, the combination of technical measurement science and consumer sensory characterization is critical. The rheological technical measurements described throughout this discussion can be used in conjunction with consumer sensory testing.

Quantitative Descriptive Analysis, QDA, for sensory characterization of consumer products (18) was used for the subjective evaluation of emulsion attributes, during and after rubbing the emulsion over the skin, for five subjective parameters defined as:

- Cushion (thickness): is the amount of material being felt between the fingertips and the skin while making the three rotations with the respective finger. 1 is designated as the thinnest, 6 as the thickest.
- Quickness of break: defined as how fast the emulsion structure breaks down. This is typically characterized by a cooling or wet sensation. 1 is

designated as the slowest to break (more rubs), 6 as the fastest to break (less rubs).

- Wetness: the amount of perceived wetness during the three rotations (when structure is most likely starting to break or has been broken) with the fingers. 1 is designated as the least wet, 6 as the most wet.
- Spreadability: the ease with which the product is spread over the skin. 1 is designated as the most difficult to spread, 6 as the easiest to spread.
- Afterfeel intensity (residue): is the perceived amount of material left covering the skin. 1 is designated as the least residue, 6 as the most residue left on skin.

The results of the sensory characterization study are shown in Figure 26.

Figure 26. Quantitative Descriptive Analysis, QDA, for sensory characterization of the skin care emulsions in Table 3, as a function of the type of carbomer polymer.

The effect of differing carbomer polymer chemistries on the overall sensory attributes of the emulsion is significant. For instance, the data indicate that the

emulsion prepared with Carbopol® Ultrez 20 polymer gives the most cushion, it feels less wet and it does not break down readily, it offers more resistance to spreading, and it is perceived to leave residue after application. On the other hand, the emulsion prepared with Ultrez 10 is perceived as wet, it spreads and breaks easily, and leaves less residue. In sum, the sensorial characteristics of the polymers can be compared and ranked as follows:

1) Cushion: Ultrez 20> Ultrez 21=CBP934=CBP980>CBP940> Ultrez 10
2) Quickness of break: Ultrez 10>CBP940> CBP934>CBP980= Ultrez 21> Ultrez 20
3) Wetness: Ultrez 10>CBP934= Ultrez 21>CBP980>CBP940>Ultrez 20
4) Spreadability: Ultrez 10>CBP940>CBP980=CBP934= Ultrez 21> Ultrez 20
5) Afterfeel intensity: Ultrez 20> Ultrez 21>CBP980=CBP940>CBP934> Ultrez 10

The sensory attributes of the emulsions correlated with many of their rheological properties. For instance, in general the perception of wetness, quickness of break, and spreadability seem to be attributes of the emulsions prepared with carbomer polymers with the high sensitivity to electrolyte such as Ultrez 10, CBP940, CBP980, and CBP934. The emulsions formed with these polymers under the presence of NaCl have relatively low viscosity and low elastic modulus. On the other hand, the emulsions formed with polymers such as Ultrez 20 and 21 gave more cushion, were more difficult to spread, and were perceived as less wet. These polymers gave emulsions with high modulus and their viscosity was less sensitive to electrolytes.

4.2.2.6 POLYMERIC RHEOLOGY MODIFIERS IN HYDROALCOHOLIC FORMULATIONS

Many consumer products utilize a hydroalcoholic solvent system. Such products include alcohol hand sanitizers, sunscreen gels, and hair-styling products. The interactions of polymeric rheology modifiers and the solvent system are critical for providing the rheological needs of such systems: viscosification and shear-thinning flow behavior.

The viscosity of a hydrophobically modified AMPS®-based polymer, Aristoflex® HMB, in various organic solvent/water systems was evaluated my Morschhauser et al. (Figure 27). The viscosity as a function of organic solvent concentration was studied for three organic solvents: 1,2 propylene glycol, ethanol, and acetone (11).

Figure 27. Viscosity of 1% Aristoflex® HMB solution in water/solvent mixtures. Brookfield viscometer, 20°C.

The viscosity of 1% Aristoflex® HMB in deionized water was approximately 50,000 mPa·s. The addition of 1,2 propylene glycol did not significantly affect the viscosity up to a 70:30 ratio of 1,2 propylene glycol:water. The combination of ethanol and water showed an initial decrease in viscosity at a 20:80 ratio of ethanol:water. The viscosity decrease with addition of ethanol was approximately linear up to 60% ethanol where a more significant viscosity decrease was observed. Acetone had the most significant impact on viscosity with an initial decrease in viscosity with addition of 10% acetone and a continued decrease in viscosity with an increase in acetone concentration. A significant decrease in viscosity from about 15,000 mPa·s to about 2,000 mPa·s was observed between 60% and 70% acetone, respectively. These differences in organic solvent effect on viscosity can be directly attributed to the interaction of each solvent system with the Aristoflex® HMB polymer.

Of the above water/solvent systems, the ethanol/water solvent system is most commonly used in personal care formulations. The effect of polymer concentration on the viscosity of these systems was evaluated in 62% ethanol/water gels (Figure 28).

Figure 28. Viscosity of Aristoflex® HMB solution in 62% ethanol/water mixture.

At Aristoflex® HMB concentrations below about 1.25%, the viscosity of the gel is less than about 30,000 cP. Above about 1.25% polymer, the viscosity of the gel increases significantly, reaching about 650,000 cP at 2.0% Aristoflex® HMB. This is typical behavior of polymers in solvent. Below a critical polymer concentration, known as the critical overlap concentration (c*), polymer molecules do not interact with one another in solution. As polymer concentration increases, a concentration is reached where polymer molecules begin to overlap and then entangle, which exponentially increases the viscosity. The concentration where polymers begin to overlap is c*. The value of c* for Aristoflex® HMB in 62% ethanol/water is approximately 1.25% polymer.

Generation of a graph of viscosity as a function of polymer concentration, in the chosen solvent system, can aid in determination of the appropriate polymer concentration to provide the desired product viscosity. It can also aid the formulator in understanding the sensitivity of the formulation to small deviations in polymer concentration that may be encountered during manufacturing. It is critical if attempting this technique, that the formulator consider other components of the formulation that may affect the viscosity and polymer-solvent interactions. The viscosity as a function of Aristoflex® AVC polymer concentration in a full formulation, containing 62% ethanol/water plus silicones and emollients, is shown in Figure 29.

Figure 29. Viscosity of Aristoflex® AVC containing formulation in 62% ethanol/water mixture. Formulation also contains silicones and other emollients.

The viscosity increases exponentially after a critical polymer concentration of about 0.8% Aristoflex® AVC. The viscosity increase above the c*, 0.8% Aristoflex® AVC, is more gradual in the full formulation compared to a simple gel due to the complex environment with the inclusion of silicones and emollients.

In the case of thickening of hydroalcoholic solutions with carbomer polymers, the critical factor is to be able to select the correct base neutralizer for the amount of alcohol that is to be gelled. Since Carbopol® polymers contain unneutralized carboxylic acid groups in their backbone, these could be neutralized with practically any base to affect the solubility or degree of swelling of the polymer in hydroalcoholic solutions. If the wrong neutralizer is used, the salt of the Carbopol® polymer will precipitate out because it is no longer soluble in either the water-ethanol or water-isopropanol blend. Table 4 gives recommended neutralizers for various alcohol levels.

Table 4: Recommended Neutralizers for Hydroalcoholic Systems

Alcohol wt%	Neutralizer
20%	Sodium Hydroxide
30%	Potassium Hydroxide
60%	Triethanolamine
60%	Tromethamine
80%	Aminomethyl Propanol
90%	Tetrahydro-xypropyl Ethylenediamine

Alcohol wt%	Neutralizer
90%	Diisopropanolamine
90%	Triisopropanolamine
>90%	PEG-15 Cocamine

This indicates that for hand sanitizers containing 60% to 90% parts of ethanol or isopropanol, highly viscous and clear compositions can be easily obtained by using 1 wt% of a carbomer polymer using triisopropanolamine as the neutralizer to achieve pH 7.5.

4.2.2.7 POLYMERIC RHEOLOGY MODIFIERS IN OPTICAL EFFECTS CLEANSING FORMULATIONS

The rheological needs of surfactant-based systems are unique compared with organic solvent systems or emulsion systems. Consumer preference for a cleansing product is typically for Newtonian flow behavior so that the product pours easily from the bottle and is evenly distributed on the skin or hair surface before dilution and lathering can begin. Newtonian flow is achieved in surfactant systems by micellar thickening mechanisms, such as high surfactant concentration or salt thickening. Viscosifying polymers, such as PEG-150 distearate, can also provide Newtonian rheology in surfactant systems. These mechanisms for thickening and providing Newtonian flow cannot be used in optical effects cleansers where a yield stress is required to suspend particles, beads, or air bubbles. In these systems it is critical to provide a yield stress for suspension stability while maintaining a low viscosity so that the product is pourable. This is achieved using polymeric rheology modifiers whose function in the formulation is to provide this critical yield stress for suspension.

Miller and Loeffler studied the suspension capability and the viscosity of a model surfactant system comparing a polymeric rheology modifier (Aristoflex® HMB) and sodium chloride, Figure 30 (17).

Both the Aristoflex® HMB and NaCl increased the viscosity of the surfactant system. Aristoflex® HMB exhibited a c* of about 1.2% AMPS®-Beheneth-25, above which the viscosity was in a typical cleansing product viscosity range. This same viscosity range was achieved with approximately 4–5% NaCl. Particles with an average diameter of 850 μm and density of 0.03 g/cm^3 were suspended in each surfactant formulation. The stability of the particles was evaluated visually and is labeled as either “creaming” (unstable) or “stable” in Figure 19. It is evident from Figure 19 that viscosity alone cannot provide stable suspension of these particles. The Aristoflex® HMB imparted a low yield stress in addition to viscosity, which provides suspension stability, Figure 31 (17).

Figure 30. Viscosity and stability to creaming of Aristoflex® HMB and NaCl containing shower gel formulations.

The critical polymer concentration, c_τ, required for suspension stability was determined to be approximately 0.3% Aristoflex® HMB, using a visual stability method. Therefore, the yield stress will be high enough to suspend the particles at polymer concentrations above 0.3% Aristoflex® HMB. However, 1.0–1.5% Aristoflex® HMB was required to provide a consumer-desired viscosity (Figure 19). Stable suspension of particles throughout the formulation is necessary to connote the consumer benefit and to make a visually appealing product.

ASE and HASE-type polymers can also be designed to provide extended shelf life to optical effects cleansing formulations. Carbopol® Aqua SF-1 has a relatively high yield stress under most conditions of formulation. To illustrate the suspending power of the polymer in a surfactant composition such as a facial scrub, a cocktail of water-insoluble particles was added to the formulation to observe particle sedimentation or creaming. Table 5 shows the compositions of the mixture of particles, which include a range of particles with various diameters and specific gravity that are commonly used in the formulation of personal care products.

Figure 31. Yield stress and stability to creaming of Aristoflex® HMB in shower gel formulation.

Table 5: Composition of the mixture of particles used to test the stabilizing effect of ASE and HASE polymers

Type	**INCI Name**	**Specific Gravity**	**Particle Size µm**
Glitters	Synthetic Fluorphlogopite and Titanium Dioxide and Iron Oxides	2.9–3.2	20–95
	Synthetic Fluorphlogopite and Iron Oxides	2.9–3.2	95–730
Polyethylene	Polyethylene	0.92	0–315
	Polyethylene	0.92	400–800
Unispheres®[23]	Mannitol and Cellulose and Hydroxypropyl Methylcellulose and CI 77289 and Tocopheryl Acetate	1.1–1.2	1000–1500
	Mannitol and Cellulose and Hydroxypropyl Methylcellulose and CI 77492 and Tocopheryl Acetate	1.1–1.2	500–900
Jojoba Beads	Jojoba Esters and CI73360 and Talc	0.9	250–600
Floraspheres®[24]	Jojoba Esters	0.9	1200–1700
Natural scrubs	NA	>1	NA

The mixture of particles was added at about 1% wt. to a model facial wash surfactant composition with a target viscosity (Brookfield RVT @ 20 rpm, 25°C) of 8,200 cP and pH 5.4.

To assess the stabilizing ability of the polymer, samples of the model facial wash surfactant composition were kept at 45°C for one week. The suspending ability of the polymer was assessed visually by observing the migration or agglomeration of the suspended particles in clear glass containers. The following scores were used to assess the shelf life of the formulation with respect to stabilizing the suspended particles.

Scores for suspension:

4 = good, suspended

3 = fair, slight sedimentation

2 = poor, half sedimentation

1 = very poor, not suspended at all

The results of this test are shown in Figure 32 and Figure 33 where various ratios of copolymers SF1 and NL10 were added to the formulation as rheology modifiers and suspending agents. It can be observed that good suspension is obtained when SF1 is the only suspending agent (ratio = 100/0) added to the composition. At ratios greater than 80/20 of SF1 to NL10, the suspending ability of the system is still good. However, as the concentration of NL10 increases, the suspending power of the system becomes rapidly deficient in spite of the significant gains in Yield Value and viscosity. These data underscore again that measuring the yield stress of a formulation requires careful consideration and interpretation. Furthermore, the methods to measure yield stress require proper validation by conducting shelf-life studies on the formulation in question.

Figure 32. Suspending ability of polymers in a Facial Wash Formulation containing a total amount of 1.8 wt% polymer at various ratios of Carbopol® Aqua SF-1 / Novethix™ L-10 Copolymer. BYV = (η @ 0.5 rpm - η @ 1.0 rpm) / 100, pH = 6.6. All measurements on samples aged for one week at 45°C.

Figure 33. Viscosity and Brookfield Yield Value, BYV, of the Facial Wash Formulation containing a total amount of 1.8 wt% polymer at various ratios of Carbopol® Aqua SF-1 / Novethix™ L-10 copolymer. Data obtained with RVT Brookfield Viscometer rotating at 20 rpm, 20°C, pH 6.6 adjusted with NaOH. All measurements on one week at 45°C aged samples.

CONCLUSION

Rheological properties of all formulation types affect the consumer's perception of the product. The stability of the product is critical to formulators to successfully bring a product to their consumer. The viscosity, shear behavior, yield stress, and viscoelasticity are critical rheological parameters that impact the product's visual aesthetics and in use-sensory properties. Understanding the effect of your rheology modifier on all aspects of the product's function can improve the design of your product and aid in delivering consumer-preferred formulations that connote the desired or claimed product benefits.

ACKNOWLEDGEMENTS

We would like to say a big "Thank You" to all those people without whose competent ideas, suggestions, and data, it would have impossible to prepare this chapter.

ABSTRACT

Silicone polymers have been known since 1880, however they did not become a major ingredient in the personal care industry until the 1990s. The designation "silicone polymers," as will be seen in this chapter, covers a variety of silicon-based materials that are characterized by molecules or polymers that contain the Si-O-Si bonds. For convenience, and ease of introducing these materials to you the reader, we have initially simplified our speaking about these materials to "silicone polymers." However, one of the goals of this chapter is to distinguish that "silicone polymers" actually represent a whole range of materials ranging from

simple silicon-based molecules (e.g., silanes) to "straight" polydimethyl siloxane polymers (of varying molecular weight to linear and cyclic variations of these; to "organosilicone" copolymers of different chemistries (like "T" configurations or "ABA" type polymers; to cross linked variations of silicon-based materials which vary in the degree of cross-linking to generate yet another class of gelled "silicone polymers" of varying degrees of rheological behavior and applications in the personal care and cosmetic industries. Further, as we delve deeper into this enormous and widely useful class of materials in the cosmetic and personal care industry, one of our intentions is to make sure that the "old" use of the term "silicone copolyol" (from its initial INCI definition), disappears forever since there is no one such material as "silicone copolyol!"

We also address the apparent trend away from "silicones" in light of their reputation as useful, but not "natural"—and how the technology is evolving to deal with this issue without losing the unique properties the materials are famous for. Further, the chapter addresses the potential toxicity question of very low molecular weight cyclic silicones, which provide a unique, noncooling effect on evaporation and alternatives to these cyclic silicones known as cylcomethicone (D4 and D5).

PREFACE

Silicones have become ubiquitous in our industry and, in fact, there are few product categories that do not have "silicone" present. This fact has been made abundantly clear by the rapid growth in the number of patents related to silicone ingredients and their compositions. We also note their use in formulations for numerous cosmetic and personal care categories and the many synergistic effects obtained with other components.

There are a few key, unusual functional attributes that make silicone a "must have" in a personal care formulation. These include: better surface tension reduction than that obtained with organic surfactants and, at much lower concentrations; as well as the capability of the forming associative films upon dry-down. Further, in view of the presence of the silicone moiety, these materials have expanded emulsification properties beyond those of organic surfactants. They also have foaming ability in both aqueous and nonaqueous environments the capability to disperse pigments, and an ability to generate a desirable, unusual sensory/aesthetic silky feel.

As we have stated above, silicones provide an outstanding feel and unparalleled sensory performance that a formulation would be lacking without the presence of silicone. This chapter addresses the selection process, which is drawn from a host of molecular choices that vary in their structure and stereochemistry.

4.2.3.11 INTRODUCTION

Silicones can drastically change the performance of a cosmetic formulation by the modification of two salient properties: (1) insolubility in both hydrocarbon oils and water, as well as (2) surface and interfacial properties when hydrophilic and hydrophobic moieties are present. While these two properties seem simple enough, a good understanding of the two, and the value they bring to formulations, is key to the proper selection of organosilicone polymers in order to obtain specific desirable properties. In short, silicone polymers should be used in a formulation only when they provide benefits not provided by other classes of polymers.

Today, the global consumer is faced with many often-contradictory desires when selecting a cosmetic or personal care product. The cosmetic industry is driven by the consumer in the sense that if a cosmetic formulation does not feel good on topical application, they will not buy it no matter how well it performs. As we enter the "Green Chemistry" age, consumer demands have evolved and changed towards use of natural products. The desire for formulations that are "green" has become a major focus when formulating a cosmetic formulation. While the definition of green chemistry has been debated and will be addressed later in this chapter, one thing is clear: Consumers are looking for products that are "green," and contain a greater percentage of sustainable raw materials. This push towards green products has some limitations; none bigger than the fact that while the consumer wants a green product, the demand for cost-effective performance still remains. This dichotomy, and schism, makes the proper selection of silicone-based raw materials even more critical. It is commonly accepted that silicone is not green. This leads to the concept that silicone compounds should be incorporated into cosmetic formulations in minimal concentrations. Essentially, formulations utilize silicone to drive performance upwards and not as a main ingredient. This means that judicial selection of the most efficient silicone will be used in formulations, and silicone- based products will be used only when other less costly options are unavailable. Determining the efficiency of silicones in formulations is an absolute requirement, and this chapter provides insights on methodologies to fine-tune formulations and achieve the optimal balance between perception, cost, and performance.

4.2.3.12 SOLUBILITY

It is important to understand that the term "silicone polymer" refers not to one material but to many classes of products. The simplest class is a polymer that contains only dimethylpolysiloxane, and this term generally refers to the term "silicone fluids." Other classes of silicone polymers contain organic groups besides, or in place of the methyl groups and are referred to as organo-functional silicone polymers. One of the unique properties of silicone fluids is the fact that they are insoluble in

both water and oil (Figure 2.0.1). Since oil and water are two of the most common ingredients in cosmetic formulations, how they interact with the silicone polymers is a significant key to formulation performance.

Figure 2.0.1: Solubility

This difference in solubility from both water and hydrocarbon oil has long been an invitation to the chemistry community to rethink the terms "hydrophobic" and "hydrophilic." In the cosmetic and personal care world, in which there are primarily only two immiscible phases, oil and water, the terms hydrophilic and hydrophobic are sufficient. In fact the whole concept of hydrophilic/lipophilic balance (HLB) by Griffin (discussed at http://en.wikipedia.org/wiki/Hydrophilic-lipophilic_balance) has been eminently useful to describe the behavior of "organic" surfactants.

When the silicone moiety is introduced, new terms become necessary. This is due to the fact that a hydrophobic material can be either oil-loving (oleophilic) or silicone-loving (siliphilic).[i] The term "group opposites" has been applied to this concept.[ii] Table 2.0.1 shows the classifications.

Table 2.0.1

Solubility Characteristic Terms	
Hydrophilic (water loving)	Hydrophobic (water hating)
Oleophilic (oil loving)	Oleophobic (oil hating)
Siliphilic (silicone loving)	Siliphobic (silicone hating)

There are several new terms introduced in Table 2.0.1. With these distinctions, materials can now be broken down into more specific categories. A hydrophobic (water-hating) product can be either oleophilic or siliphilic. Oleophobic (oil -hating) materials may be either hydrophilic or siliphilic. Siliphobic (silicone-hating) materials may be either oleophilic or hydrophilic. If a hydrophobic or siliphobic fiber is treated with "silicone" or with a hydrocarbon, the fiber will become oleophobic at the surface. Thus, for application in waterproofing fibers, selection of the proper solubility characteristics is critical.

4.2.3.13 SURFACE TENSION

The other unique and salient characteristic of silicone compounds, either silicone fluids or silicone polymers containing other functional groups (i.e., organo-functional) is the fact that silicone-containing polymers have much lower liquid/air surface tension as compared to hydrocarbon oils and water. Surface tension has been defined as: "the energy required to break through the surface of a substance."[iii] In a bulk solution, the molecules at the air/solution interface behave differently than a molecule in the bulk solution. This leads to superior surface-active properties. An interesting example of this behavior is that of water. Water, at the air/water interface has a high surface tension (72 dynes/cm), leading to a high boiling point (100°C) and the ability to suspend a paper clip gently placed upon its surface! This high boiling point is surprising because of the low molecular weight of water (18 g/mol). The major reason why the surface tension of water is so high is because of hydrogen bonding. When compared to hydrocarbon oils and water, their surface tension is significantly lower than that for silicone. Table 3.0.1 shows typical surface tension values.

Table 3.0.1[iv]

Surface Tension	
Material	**Surface Tension (dynes/cm)**
Mercury	472.0
Water	72.6
Squalane	46.2
Soap Solution (1%)	38.8
Mineral Oil	33.1
Dimethicone (i.e., polydimethyl siloxane)(20cP)	26.6

Surface Tension	
Material	**Surface Tension (dynes/cm)**
Acetone	23.7
Hexamethyldisiloxane	22.7
Ethanol	22.2
Cyclomethicone (cyclic silicone with 4 repeating units of O-Si-O(D4)	20.6
Diethyl ether	17.0

The low surface tension demonstrated by polydimethlysiloxane relates directly to its structure, how the molecules orient at the liquid/air surface, and the intermolecular forces. Silicone fluid is a silicone polymer consisting of repeating units of Si-O [–(O-Si$(CH_3)_2)_n$-]; its structure is shown below (Figure 3.0.1).

Figure 3.0.1: Structure of Silicone Fluid (Polydimethylsiloxane)

Silicone fluid (polydimethylsiloxane) does *not* have strong intermolecular forces, and the only intermolecular forces it possesses are dispersion forces that refer to their superior ability to spread out on surfaces. Furthermore, the silicone polymer has very flexible Si-O bonds in the polymer backbone, and is highly branched due to the methyl groups. This branching affects the way the polymer chains interact with one another. The presence of methyl groups on the polymer prevents chains from packing tightly, thus decreasing surface tension. Figure 3.0.2[ii] shows a computer-generated structure for a silicone fluid. The polymer is known to coil up on itself, much like DNA, and this may be visible, somewhat, in Figure 3.0.2 below.

Figure 3.0.2:[ii] Silicone Surfactants (Organo-Functional Silicones)

Surfactants are a class of compounds commonly used in cosmetic formulations. An extensive discussion of surfactants is presented elsewhere in this text. Surfactants have been defined as: substances that change the properties of a surface.[3] When a surfactant is added to a solution in which it has some solubility, it migrates to the air/liquid interface. This migration causes a disorder in the surface wherein the hydrophobic portion is ejected from the liquid (water), thus decreasing surface tension since the interface now appears hydrophobic. Below is a graphic of how surfactants lower the surface tension of a material.[5] The graphic covers a range of surfactant concentration from below the critical micelle concentration (i.e., not enough to entirely cover the air/liquid surface) to higher levels where the surface is filled and excess surfactant is pushed under the surface, migrate to each other and form "micelles," which are clumps of surfactants with their outside consisting of the surfactants' hydrophilic portion and the inside of the micelle consisting of their hydrophobic portions.

Altering the surface tension of materials provides many of the desirable properties that silicone copolymers bring to cosmetic products as outlined in Table 3.0.2.

Table 3.0.2

Desirable Properties of Silicone Polymers
1. Skinfeel
2. Spread
3. Film Formation
4. Dry feel

Further discussion of critical micelle concentration (CMC) and how silicone affects the surface tension of a bulk solution will appear later in this chapter.

4.2.3.14 SILICONE NOMENCLATURE

Silicone fluids are polymers made up of building blocks or monomers. The word "polymer" can be broken down into "poly" meaning many and "-mer" meaning unit. Typically silicone polymers are is made up of repeating silicone oxygen bond units. These "repeat" units are called monomers and they have to be at least di-functional. When these monomer units react with themselves they can either form a linear polymer chain (silicone fluid) where the more of them that react, the higher the molecular weight (into the millions for silicone rubber), or rings that are coined (cyclics). Cyclics are essentially polymer chains that form when one end group reacts with the other, forming a ring. There are several common building blocks, so named by how many silicon-oxygen bonds they contain. Figure 6.0.1 below contains a list of the most common building blocks used in silicone polymers.[6] The figure also shows a shorthand designation for each structure that is quite useful in describing these complex materials: M, D, T, and Q.

As seen in the table, each building block is named by how many silicon-oxygen bonds it has; "M" units or mono-substituted groups are "chain terminators." They only have one reactive site, so they have to be on the end of the polymer chain, or as a pendant group of the silicone polymer chain. Pendant groups are groups that "hang" off of the main polymer backbone or polymer chain. M units cannot be in the silicone polymer backbone because they only possess one reactive group. Unlike the M unit, the D unit is di-substituted and will be found in the polymer backbone. The T and Q units are used as cross-linkers, linking two or more polymer chains together. Typically, chemists refer to silicone polymers as silicone fluids and identify their structures by their letters and viscosities. An example of this is $MD_{50}M$. The structure of this polymer is shown in Figure 6.0.2.

Building Blocks		
Name	Structure	Numer of Si-O bonds
M Mono-		1
D Di-		2
T Tri-		3
Q Quat-		4

Figure 6.0.1

Structure of $MD_{50}M$

Figure 6.0.2

$MD_{50}M$ is a silicone polymer made up of 50 D units, end-capped with M units. It is synthesized by the reaction of MM with cyclic D_4 or D_5. A detailed discussion of cyclo-silicones and fluids will appear later in this chapter.

It must be clearly understood that the chlorosilane materials made in the Rochow process result in the building blocks that are found in the polymers and for which the nomenclature is derived.

All of the units mentioned so far are useful for synthesizing silicone fluids or nonfunctionalized (e.g., with organic groups, for example) silicone fluids. To functionalize silicone polymers, new building blocks with reactive sites are needed. Figure 6.0.3 outlines some of the common reactive building block sites. These are stereochemical positions created by the basic starting structure where other reactive materials can be attached. One example of this would be a short hydrocarbon chair, or a short chain of polyethylene glycol or, getting more complex, low-molecular-weight copolymers (either random or block) of ethylene oxide and propylene oxide.

Reactive Building Blocks			
Name	Structure	# of Si-O bonds	# of Reactive Sites
M* Mono-		1	1
D* Di-		2	1
T* Tri-		3	1

Figure 6.0.3

It is important to note that there is no Q^* reaction site shown. The Q building blocks have four silicone-oxygen bonds and therefore they cannot have a reactive site bonded to them. However, even these can be reacted with M end blockers to make MQ resins, which also are another type of silicone gels that have found usefulness in cosmetics.

Silicone polymers can contain from one to several reactive sites. They are typically constructed by reacting either M^*M^* with a cyclic, a reactive cyclic with MM, or M^*M^* with a reactive cyclic. Reactive cyclics are typically denoted as D_{5*}.

They follow the same nomenclature as above. If we take the polymer from above (MD_{50}) and add reactive sites, its name gets changed to $MD^{*}_{50}M$. The structure is shown in Figure 6.0.4.

Figure 6.0.4

These reactive sites can be placed at three parts of the polymer backbone. They are named after what the polymer resembles following the reaction. Figure 6.0.5 shows illustration of the three common structural types.

Name	Illustration
1. Comb	
2. Terminal	
3. Star	

Figure 6.0.5

Theses three categories are so named by the theoretical shapes of the polymer backbones. The first category is called comb. This is because when the chemist draws out the structure it appears like a hair comb. All of the reactive sites are on one side (pendant) and along the backbone of the polymer or comb. It should be taken into consideration that the polymer backbone has free rotation and the reactive groups can be in many different arrangements when the polymer chain is in motion. The second category is so named terminal. This category is self-explanatory by the fact that the only reactive groups on the polymer are at the chain ends. The final category is the star category. This category is so named because it could be envisioned that this polymer chain would have reactive groups on all sides of it and at the ends. Such molecules grow outward from a center in a multiplicity of "arms."

It is important to note that the functional group shown above is the Si-H bond. This is not the only reactive site used in the synthesis of functional silicones. There is a long list of functional groups that can be incorporated to fully utilize silicone chemistry.

a. Summary of Silicone Polymer Structure Types

The silicone backbone that is prepared by the technology developed by Rochow makes up what is called the *construction* of the silicone polymer. It is the number and location of the so-called Ds, Ms, Ts, and so on that determines one major part of the function of the polymer. The other parameter that helps define the structure-function behavior of these materials is called *functionalization* and is determined by what the M*s D* and the like *are reacted with* to make organo-functional silicones. There are indeed a great number of products that can be made using this technology.

4.2.3.15 VOLATILE SILICONES

Volatile silicones comprise a class of compounds that have a low heat of vaporization; that is, they evaporate from skin easily, providing a cooling effect. Evaporation of a material from the skin causes a cooling effect. Cyclomethicones conform to the structure shown in Table 7.0.1.

Table 7.0.1

Cyclomethicone			
Structure	**N**	**Common Name**	**Name**
	3	D3	Cyclotrisiloxane
	4	D4	Cyclotetrasiloxane
	5	D5	Cyclopentasiloxane
	6	D6	Cyclohexasiloxane

The INCI name "cyclomethicone" refers to a family of cyclic dimethyl siloxanes that includes cyclotetrasiloxane (D_4), cyclopentasiloxane (D_5), and cyclohexasiloxane (D_6), a family that has come under increased environmental/regulatory scrutiny in recent years. Cyclomethicone compounds are commonly used in cosmetic products to provide a solvent that feels dry on the skin. Key areas where this family of materials is used include antiperspirants, color cosmetics, and as a base solvent to blend with fragrance oils and perfume oils. Cyclomethicone is a clear, odorless silicone that leaves a silky-smooth feel when applied to the skin. Cyclomethicone compounds possess a cyclic structure rather than the chain structures of linear dimethyl silicones (dimethicone). D_4 evaporates from the skin and is volatile, resulting in a lower heat of vaporization, but it also has a very low surface tension. In other words, the volatility of D_4 is only one of the reasons it has a dry skin feel, but its low surface tension resulting in spreadability on the skin cannot be ignored. However, the physical chemistry that results in the dry feel of cyclomethicone evaporating is a complex one. Volatility is but one aspect of the complex phenomenon that contributes to a dry feel in a solvent used in cosmetics. In view of the safety concerns associated with the low-molecular-weight cyclomethicones, replacements have been sought. These must also provide similar viscosity and surface tension reduction (which affects spreadability), and must be nonflammable and cost effective (a formidable combination!). Clearly, a D_5 replacement that is flammable, defatting, and expensive is unacceptable. Table 4.2 shows the Heat of Vaporization of some compounds. Table 7.0.2 shows that it takes significantly less energy to evaporate D_4 or D_5 than either water or ethanol.

Table 7.0.2[7]

Heat of Vaporization	
Materials	**Heat of Vaporization (cal/g)**
Water	539
Ethanol	210
D_4	31
D_5	31

The cyclic silicones in Table 7.0.2 have a dry feel when applied to the skin, for two main reasons. First, they have the ability lower surface tension of the formulation, containing oil and thereby leading to a drier-feeling product, since they are surface active in oils. Second, since the cyclics are so volatile, they evaporate rapidly when they are exposed to the temperature of the skin. There are a number of cosmetic applications in which a dry skinfeel is important. These include antiperspirants, skin serums, and sun-care products. Table 7.0.3 shows some other characteristics of cyclic silicones.

Table 7.0.3

Cyclic Silicones					
INCI Name	**Viscosity (cS)**	**Molecular Weight (g/mol)**	**Solubility Parameter**	**Refractive Index**	**Flash Point (°C)**
Cyclotetrasiloxane	2.5	297	7.4	1.394	55
Cyclopentasiloxane	4.2	371	7.4	1.397	76
Cyclohexasiloxane	6.8	445	7.4	1.399	93

Recently, the use of D_4 in personal care applications has been abandoned because of safety concerns. The most common replacement has been D_5, and to a lesser extent, D_6. While drawn from the same family, these materials have different physical properties and do not result in the same dry feeling as D_4.

Cyclomethicone is used in a variety of products. From a commercial view, most importantly they have been used in antiperspirant formulations because they:

(1) Impart a soft-silky feel to the skin
(2) Provide excellent spreading
(3) Leave no oily residue or buildup
(4) Detackify formulations
(5) Are nongreasy
(6) Are compatible with a wide range of cosmetic ingredients
(7) Lower surface tension and
(8) Provide transient emolliency on the skin.

Cyclomethicones are used in many other applications including:

Table 7.0.4

Cyclomethicones in Cosmetic Application
1. AP / DO
2. Hair Sprays
3. Cleansing Creams
4. Skin Creams, Lotions
5. Stick Products
6. Bath Oils
7. Suntan
8. Shaving Products
9. Makeup
10. Nail Polish

a. Cyclomethicone Replacements

As we have said, over the years, the cosmetic industry has been actively seeking cyclomethicone replacements. D_4 is no longer used in our industry and despite some indications that the underlying conclusions that it is problematic in cosmetic products is faulty, the consumer simply will not accept these materials in formulation. The sharp consumer sensitivity to cosmetic formulation additives will also have an effect on D_5. While it is guilt by association, it is my feeling that long-term D_5 will also disappear. Products that contain large quantities of D_5 will be first to feel the wrath of consumers. In fact, in the future the use of silicone in formulation will be limited to those polymers that (a) provide a function that is not attainable from other types of materials and (b) are effective at very low concentrations. Put metaphorically, if a cosmetic product is a gourmet meal, the silicone additives will be the spice to the meal and not the meat and potatoes.

One approach to cyclomethicone replacement is to use low-molecular linear dimethicone. The most common linear polydimethylsiloxane (dimethicone) used to replace the cyclics range from 0.65 cSt to 3 cSt fluid. Despite the added cost, of these materials over that of cyclomethicone, they have enjoyed some success because of their similar properties. (See Table 7.1.1.)

Table 7.1.1

D5 Replacements				
INCI Name	**Hexamethyl Disiloxane**	**Dimethicone**	**Dimethicone**	**Dimethicone**
Viscosity (cSt)	0.65	1.00	1.50	2.00
Molecular Weight	162	236	311	385
Specific Gravity	0.76	0.82	0.85	0.87
Refractive Index	1.375	1.382	1.387	1.389
Solubility Parameter	6.7	6.9	7.0	7.0
Flash Point (°C)	–3	34	56	87

Another approach to replacing cyclomethicone is to use a silicone that is a methicone and not a dimethicone. Dimethicone compounds contain a dimethylsiloxane group; methicone compounds contain only mono methyl silioxanes wherein the other methyl group is replaced with a non-methyl organo-functionality. These polymers are not made from D_4. When a properly selected methicone is added to triglycerides or other esters, such a material: (1) will lower the surface tension at low concentration, making esters and triglycerides feel more like silicone; and (2) can be used in an ester or triglyceride at less than 5 percent, providing a cost-effective D_5 like feeling.

Methicone

R is $-CH_2CH_3$

The desirable dry effect achieved on the skin by the efficient reduction of surface tension of a natural oil, or low-viscosity ester, by means of using low concentrations of ethyl methicone offers a valuable formulation tool for the formulator. Replacing D_5 with combinations of natural oils and a small amount of alkyl silicone results in a replacement that is greener than D_5 (due to the fact that natural oils are present). Table 7.1.2 shows an example of how D_5 can be replaced by another silicone in an antiperspirant formulation.[6]

Table 7.1.2

Antiperspirant Formulations[8]			
Material	**Formulation**		
	A	**B**	**C**
Part A			
Aluminum/Zirconium Tetrachlorohydrex-gly	24.000	24.000	24.000
PEG/PPG 18/6 Dimethicone	2.500	2.500	2.500
Part B			
Cyclopentasiloxane	30.000	0.000	0.000
Ethyl Methicone	0.000	30.000	1.500
Glycine SoJa (Soybean Oil)	0.000	0.000	28.500

Antiperspirant Formulations[8]			
Material	**Formulation**		
	A	**B**	**C**
Part C			
Isohexadecane	9.000	9.000	9.000
PPG-14 Butyl Ether	9.000	9.000	9.000
Hydrogenated Castor Oil	2.500	2.500	2.500
PEG-8-Distearate	1.000	1.000	1.000
Stearyl Alcohol	18.000	18.000	18.000
Part D			
Talc	3.000	3.000	3.000
Silica	0.500	0.500	0.500
Part E			
Fragrance (Parfum)	0.500	0.500	0.500
Total	100.000	100.000	100.00

Procedure:

1. In a side vessel, combine Phase A ingredients. Impeller mix to uniformity.
2. In main vessel, heat Phase B ingredients to 70°C under agitation. Continue mixing and add Phase A. Bring to 75°C.
3. Combine Phase C in side vessel, heat to 85°C under impeller agitation, and mix to uniformity.
4. Add Phase C to AB under homogenization. Maintain batch at 80°C.
5. Pre-combine Phase D. Add to batch under homogenization. Begin cooling.
6. Add Phase E at 70°C under homogenization. Continue cooling.
7. Pour batch into sticks at 65°C.
8. Heat-treat surfaces.

As seen in Table 7.1.3, the addition of the mixture of 1.5% ethyl methicone and 28.5% soybean oil (Formula C) functions in a very similar way to Formula A and Formula B. The inclusion of low-cost oils or esters as the majority of the D_5 replacement offers a cost-effective way to replace D_5. Soybean oil can be replaced by other triglycerides or by dry esters including capric / caprylic triglyceride.

Ethyl methicone significantly lowers the surface tension when added into an oil or ester. The lowering of surface tension of the triglyceride or ester provides outstanding feel and improves the spreadability of a formulation. Table 4.6 shows the general information of ethyl methicone.[8]

Table 7.1.3

Ethyl Methicone[8]	
Description	A polymer under REACH with a CAS number of 63148-54-9
Typical Properties	**Appearance:** Clear Liquid
	Active Content (%): 100
	Color, Gardner: 3 Max
Uses and Applications	Provides excellent dry feel and lubricity in personal care formulation. Replacement for D_4 and D_5 in applications including but not limited to antiperspirant, hair glossers, resins, moisturizers, lotions, and pigmented products. Product can also be blended with low-viscosity esters and triglycerides, mimicking a D_5-like skin feel.

b. Summary of Successful Replacements for Cyclomethicones

Volatile silicone compounds are used primarily for their dry feel and ability to deliver in a more cosmetically acceptable manner to the hair and skin. While effective and a time-honored approach, replacing cyclics in formulation has recently become a hot topic. The replacement of volatile silicones in cosmetic and personal care formulations can be very difficult, but there are several ways of approaching this problem. Replacing the volatile silicones primarily with organo-modified silicones seems to be the most viable approach at the present time. Consumer perceptions will all drive the speed at which replacements are made, but cost effectiveness, flammability, and content of sustainable raw materials will also drive what gets chosen.

4.2.3.16 SILICONE FLUIDS

Silicone fluids are a well-known and well-established class of compounds used in personal care formulations. They encompass a variety of compounds that range in viscosity from 1 to 1,000,000 cSt. Silicone fluids have an MD_nM structure as illustrated in Figure 8.0.1.

Silicone Fluid Dimethicone

Figure 8.0.1

They contain no organo-functionality other than the methyl groups, and consequently are classified as homopolymers.

Since silicone fluids have the same structure and are homopolymers, the major difference among them is their molecular weight. As the degree of polymerization (DP) is increased, so is the molecular weight and viscosity. This leads to silicone fluids being classified and sold by their viscosity. Such polydimethyl siloxanes are Newtonian (constant viscosity over a broad range of shear rates) to the point that they are used as viscosity standards. Viscosity in turn is determined by the "n" value in the formula. Obtaining the proper viscosity in a cosmetic formulation is very important to the formulating chemist.

There are two major methods for obtaining a silicone fluid with the proper viscosity. The first is to polymerize the silicone to a specific molecular weight, and the second is to blend a higher-molecular-weight silicone with a lower-viscosity one. This approach results in a bimodal distribution and generates silicone fluids that have very different properties than a mono-modal (one-silicone polymer) product made to the same viscosity. Figure 8.0.2 shows the viscosity/molecular weight relationship.[vii]

Silicone Fluids			
Viscosity at 25° C (Centistokes)	**Approximate Molecular Weight**	**Approximate "n" Value**	**Average Construction**
5	800	9	$MD_{9}M$
50	3,780	53	$MD_{53}M$
100	6,000	85	$MD_{85}M$
200	9,430	127	$MD_{127}M$
350	13,650	185	$MD_{185}M$
500	17,350	230	$MD_{230}M$
1,000	28,000	375	$MD_{375}M$
10,000	67,700	910	$MD_{910}M$
60,000	116,500	1,570	$MD_{1570}M$
00,000	139,050	1,875	$MD_{1875}M$

Figure 8.0.2

Silicone fluids are commonly used in personal care applications at low concentrations (typically < 3 % wt). Figure 8.0.3 shows some common formulations and typical use levels. It is important to note that every formulation is different, and these numbers can vary depending on the specific formulation.

Applications of Silicone Fluids[1]		
Product Type	**Desired Effect**	**Use Level (% wt)**
Skin Lotion	Desoaping	0.1
	Rub-out	0.1–0.5
	Protection	1.0–30.0
	Feel	0.5–2.0
Skin Cleaner	Lubricity	0.1–0.5
	Wetting	0.1
Antiperspirant	Anti-whitening	0.5–2.0
	Detackification	0.5–2.0
Preshave Lotion	Lubricity	0.5–2.0
Aftershave Lotion	Feel	0.5–2.0
Makeup	Water Resistance	1.0–5.0
Shaving Cream	Reduce Razor Drag	0.5–2.0

Figure 8.0.3

One common problem with formulating with silicone fluids is their compatibility with the formulation. Along with the viscosity difference between low-molecular-weight silicones and high-molecular-weight ones is that the solubility of the silicone changes drastically with molecular weight. A perfect example of this is the silicone fluids having a viscosity of up to 200 cSt. These are soluble in anhydrous ethanol, while those with a viscosity of 350 cSt and above are insoluble. A list of the viscosity of common materials is found in Figure 8.0.4.

Viscosity Comparison of Silicone Fluids[1]	
Viscosity (cSt)	**Reference Object**
1–5	Water
10	Kerosene
20	Transformer Oil
50	Sae-5 Oil
100	Sae-10 Motor Oil
350	Sae-30 Motor Oil
500	Sae-30 Motor Oil
1,000	Light Syrup
2,500	Pancake Syrup
10,000	Honey
25,000	Chocolate Syrup

Viscosity Comparison of Silicone Fluids[1]	
Viscosity (cSt)	**Reference Object**
50,000	Ketchup
60,000	Thick Molasses
100,000	Hot Tar
250,000	Peanut Butter
1,000,000	Paste/Caulk

Figure 8.0.4

a. Low-Viscosity Silicones

This class of compounds consists of silicone fluids from 5 cSt up to, but not including 50 cSt. Commonly, the viscosity includes 5, 10, and 20 cSt. They are primarily used as an ingredient in a number of personal care products due to their high spreadability, low surface tension, and subtle high skin lubricity. These fluids are clear, tasteless, odorless, and provide a nongreasy feel on the skin. They are used in a wide variety of antiperspirants, skin creams, skin lotions, suntan lotions, bath oils, hair care products, etc.

These polymers have become very attractive to replace D_5 in formulations. The aesthetics of these materials mimic the attractive properties that D_5 possesses. These properties arise from their low surface tension and their ease of spreading, giving a dry feel and lack of volatility.

b. Standard-Viscosity Fluids

Standard-viscosity fluids are all covered by the CAS# 63148-62-9. They range in viscosity from 50 to 1,000 cSt. The typical grades include 50 cSt; 100 cSt; 200 cSt; 350 cSt; 500 cSt; and 1,000 cSt.

c. High-Viscosity Fluids

High-viscosity fluids are all covered by the CAS# 63148-62-9. They range in viscosity from 10,000 to 60,000 cSt.

d. Ultra-High-Viscosity Fluids (Gums)

As their names suggest, high-viscosity fluids are called gums because of the physical properties they possess. As the molecular weight is increased, these materials become more gum-like and behave like silly putty. They have a viscosity ranging from 100,000 to 1,000,000 cSt. The CAS number for these materials is CAS 63148-62-9.

Ultra-high-viscosity silicone fluids, while very sticky in bulk, when blended with cyclomethicone and/or low-viscosity fluids provide a soft velvety feel when

applied to hair and skin. The low-viscosity fluid acts as a plasticizer in that it allows for an overall reduction of the viscosity. A brief description of the viscosity-reduction phenomenon is that the low-viscosity fluid acts like a solvent and allows the longer-molecular-weight polymer chain to move more freely. This blend of high-molecular-weight and low-molecular-weight polymers produces a product with a cosmetically elegant feel initially, but a rich velvety feel upon spreading. Generally the blend consists predominantly of low-viscosity silicone (generally 50 cSt) and is primarily about 50 to 80% by weight in the blend. These blended products improve the feel of lotion products, and provide a hydrophobic, protective, but breathable barrier to the skin that imparts a softness and emolliency to the product.

Despite the fact that ultra-high-viscosity silicone fluids are linear in structure, they have such a high degree of polymerization ("n") value that they flow very slowly. This is very typical of a high-molecular-weight silicone polymer. Typically, as molecular weight increases past a critical value called the molecular weight of entanglement, the polymer chains entangle. This entanglement restricts movement and changes the polymers' physical properties. Their linearity of structure and lack of organic functionality are salient characteristics of this class of compounds. Figure 8.4.1 shows the viscosity of an ultra-high-viscosity fluid (60,000 cSt).

Figure 8.4.1 60,000 cSt silicone fluid[viii]

e. Summary of Silicone Polymer Behavior

Silicone fluids, sometimes called silicone oils, are a class of linear polymers that range in viscosity from very low to extremely high values. While there are benefits to both extremes, there are some solubility formulating issues and differences that arise when comparing the high and low. Typically, solubility and viscosity are the primary concerns to formulating chemists. There are two common approaches

to matching viscosity and solubility: 1) direct synthesis of a molecular-weight polymer with those properties, and 2) blending a low-molecular-weight polymer into a high-molecular-weight silicone fluid. In products that are not the result of blending, the viscosity is directly related to the molecular weight, which in turn is related to the number of D units present between the two D units. As the number of D units increases, so does the viscosity and molecular weight. Blends of high-viscosity fluids with either low-molecular-weight fluids or cyclomethicone result in an efficient way to deliver the high-molecular-weight fluid to the hair or skin. The use of silicone fluids in many formulations is primarily limited by solubility.

4.2.3.17 RESINS AND ELASTOMERS

Elastomers and resins have become very interesting materials based on their physical properties. These materials are very similar and there is no set definition of what a resin is and what an elastomer is. Before we describe the difference between elastomers and resins, it is important to have a brief discussion of cross-linking and stress-induced flow behavior. Cross-linking, as the name implies, is a method that links two or more polymer chains together. Figure 9.0.1 shows an illustration of a non-cross-linked polymer and cross-linked polymer chains.

Figure 9.0.1

While the term "stress-induced flow" seems a bit complex, it is a simple concept. "Stress-induced" simply means the application of a force over a given area, which forces the polymer to move. This can be as simple as pushing your finger into a polymer. As your finger comes into contact with the polymer, it must absorb the energy of the stress (force/unit area) being applied by the tip of your finger. This is accomplished by the polymer chains slipping past one another under the applied stress. As the force of your finger is increased, once the initial barrier to movement is exceeded, the polymer chains will start to flow past one another. If

the polymer chains are cross-linked, or chemically bound together, they can only move so far away from one another. This leads to some very interesting and unique properties.

Silicone elastomers and resins contain cross-linking moieties that link two or more polymer chains together. This linking makes it impossible for the polymer chains to pass by each other. Elastomers are lightly cross-linked materials. An excellent example of this is a rubber band or the rubber used in automotive tires. When a stress is applied to an elastomer, the material will stretch. When the stress is removed, the cross-links will allow for the polymer chains to spring back into their original position. Everyone who has thrown a bouncy ball into a wall is familiar with elastomers. "Elastomers are a group of polymers that can easily undergo very large reversible elongation (up to 1,000%) at relatively low stress levels." The term "elastomeric" applies to the physical polymer properties and not its chemistry. As the degree of cross-linking is increased, the material loses its mobility and becomes very rigid. Instead of flexing like less cross-linked elastomers do, the highly cross-linked material becomes brittle and will actually snap instead of moving with the applied stress. This phenomenon leads to an important question, "When do elastomers become resins?" While the definition of the two is somewhat blurred, what is clear is the difference in physical properties. The cross-linking can be introduced in many different ways, but it is the cross-link density (the number of cross-linking groups per non-cross-linking group) that determines the eventual properties. Figure 9.0.2 show a photograph of a silicone resin and silicone elastomer.

Silicone Resin and Elastomer

Figure 9.0.2

More detailed discussion of this subject can be found in an excellent reference by Paul C. Painter and Michael M. Coleman.

Figure 9.0.3 shows some common properties of silicone gums, elastomers, and resins.

Structural Considerations[1]	
Silicone Gum	Linear Product
	No Cross-Linking
	Free Rotation Around the Si-O-Si Bond
	Oily or Sticky Feel
	No Film Formation
	Function as Plasticizers
Silicone Elastomer	Lightly Cross-Linked
	Rotation Around Si-O-Si Bond
	Provides Rubbery Films
	Provides Waterproofing
Silicone Resin	Heavily Cross-Linked
	No Rotation Around the Si-O-Si Bond
	Non-Rubbery Film
	Will Peel Off and Crumble

Figure 9.0.3

a. Resin Types

There are several types of silicone resins and elastomers. Each type is based on what groups are involved in the cross-linking process. For silicone fluids, cross-linking is limited to T and Q units. The most common types are the so-called Q resins.

b. MQ Resins

MQ resins are an extremely interesting and unique class of silicone resins. These materials possess many unique properties that are unlike silicone fluids and organic resins. They are synthesized by the reaction of monofunctional silane (M) and tetrafunctional silane (Q). The molecule has only “M” and “Q” groups, hence the name “MQ resin.” Such compounds are commonly drying to the skin and often are formulated with silicone fluids as plasticizers. The cross-linking of this type of

resin is due to the nature of the Q silane. As discussed in a previous section, the Q unit has four oxygen atoms. These four reactive sites produce a cross-linked network. The structure of these materials can be quite complex and each structure will have different properties. Huang et al. used ^{29}Si NMR to show the effect of the acid catalyst on the MQ structure.[ix] The structure of this type of product is shown in Figure 9.2.1.[x]

Graphic Representation of A MQ Resin[11]

Figure 9.2.1[11]

As depicted in Figure 9.2.1, the MQ resin forms a "cage-like" structure that forms highly organized materials. This leads to their very interesting properties both in and out of solution. The "cage-like" structure is produced only when the ratio of M to Q is low enough. As shown in Figure 9.2.2, MQ resins with a high M to Q ratio do not form a cage structure and are liquids at room temperature.

As seen in Figure 9.2.2, the cage structure does not begin to form until the ratio of M to Q reaches 2 to 1. This cage structure changes the properties of the resin dramatically.

The physical properties of these resins can be tuned by controlling the M to Q ratio. A resin with a high M to Q ratio will have liquid properties. The opposite is also true since a resin with a very low M to Q ratio will be a resin. These resins are typically soluble in hydrocarbons and can modify cosmetic products at very low concentrations.

M/Q Ratio	Structure

Figure 9.2.2

c. MDQ Resin

This type of product not only has "M" and "Q" groups, but it also has D groups, hence the name "MDQ resin." This type of material has a lower cross-link density than the MQ resin type and can be engineered to be either a resin (plastic-like) or an elastomeric (rubbery) depending upon the Q to D ratio.

d. Silicone Crosspolymers

Silicone crosspolymers are silicone polymers that are cross-linked with another silicone polymer; they can either be resins or elastomers. Figure 9.4.1 shows a schematic representation of a dimethicone/vinyl dimethicone crosspolymer.

Illustration of a Silicone Crosspolymer

Figure 9.4.1

As seen from Figure 9.4.1, each silicone polymer backbone must possess a reactive group on the polymer backbone. This means the polymer must possess a reactive site such as M^*, D^* . . . etc. In this case the cross-linker is vinyl dimethicone.

These resins/elastomers have different properties including: solubility, aesthetics, and structure. The major difference between MQ resins and crosspolymers is the structure of the polymer backbone and the structure of the finished system. Crosspolymers contain dimethyl groups on the silicone backbone. As seen above, the MQ resins form a cubic structure with each of the Q units making up the corner of the cube. The vinyl dimethicone crosspolymer is cross-linked by a much more flexible silicone polymer. These silicone polymers are composed of $Si(CH_3)_3$-O-$Si(CH_3)_2$-O- bonds, where the MQ is comprised of SiO_2 bonds very similar to inorganic silicone quarts. Table 9.4.2 shows the building blocks of the cross-linked system and the possible structures they form after cross-linking.

Table 9.4.2

Material	Structure Single Unit	Building Block	Structure
MQ			
Crosspolymer			

As seen from the illustration, the structures of these two systems are quite different, and this difference in structure leads to very different performance and application in the cosmetic and personal care field.

4.2.3.18 DIMETHICONE COPOLYOL (PEG/PPG DIMETHICONE)

At this juncture, we note that we have addressed "simple" silicones (i.e., those with no functionality such as the incorporation of water-loving or oil-loving groups attached to the silicone "backbone." As mentioned previously, silicone fluids have limited application due to their solubility properties relative to hydrocarbon oils and water. In this section we address how silicone fluids can be modified to increase their polarity and provide surfactant-type behavior at fluid interfaces. It is important to note that these modifications are done by chemical reaction between a reactive silicone and a vinyl-containing compound.

The most common modification that can be conducted to increase polarity and water solubility is to incorporate poly(ethylene glycol) (PEG), poly(propylene glycol) (PPG), or copolymers of both (either random or block type) onto the silicone polymer backbone in the so-called pendant T-configuration. After the addition of PEG or PPG, at varying positions along the silicone backbone, and in varying amounts relative to the backbone molecular weight, the silicone is called dimethicone copolyol. Dimethicone copolyols are silicone copolymers that contain at least two different polarities covalently bonded onto the same polymer backbone; in this case they have both water-soluble and silicone-soluble groups. Polymers that

possess at least two different polarities on the same polymer backbone are referred to as amphilic polymers.

When added into water at low concentrations, dimethicone copolyols (of which there are literally thousands of varieties) migrate to the air/water interface. As more dimethicone copolyol is added into the water, the interface becomes saturated and a critical point is achieved. When additional dimethicone copolyol is added, it cannot migrate to the interface, so they start to form micelles. This critical point where the interface is saturated and spherical micelles begin to form is called the critical micelle concentration (CMC). Critical micelle concentration values are determined by monitoring surface tension change with concentration. Figure 10.0.1 shows an illustration of what happens upon addition of a silicone copolyol surfactant into bulk aqueous solution.[14]

Figure 10.0.1

As seen in Figure 10.0.1, the surface tension begins to decrease in relationship with the amount of surfactant added. When the interface becomes saturated with the surfactant, the surface tension levels off and stops decreasing.

The key to surfactant efficacy in decreasing surface tension is the ability of the surface-active silicone copolymer to migrate to the interface and take up the maximum free volume on that interface. This maximization of free volume at the interface and its affinity for the interface make dimethicone copolyol extremely effective at lowering surface tension. The surface-active material distorts and packs into the lowest entropy configuration with the water-hating portions extending out of the liquid below. This leads to the dimethicone copolyol being able to be used at very low concentrations and the ability to drastically change the properties of a solution.

Dimethicone copolyols can provide many unique and desirable properties.
- Lower Surface Tension
- Provide Emulsification
- Provide Wetting
- Provide / Alter Foam
- Conditioning
- Alter Skinfeel

Dimethicone copolyols can exist in many different forms. A very common structure is shown in Figure 10.0.2.

PEG / PPG Dimethicone Structure

Figure 10.0.2

As seen in Figure 10.0.2, there are several variables that can be modified to change the performance of dimethicone copolyol surfactants. One of the most important is the ratio of a (silicone-soluble portion) to b (water-soluble portion), as well as the molecular weight of the a and b segments, which are both controllable and affect surfactant behavior. The higher the ratio of a to b, the less water soluble the organosilicone surfactant. Also, the overall molecular weight of the dimethicone copolyol can drastically change properties.

a. Wetting Properties as a Function of Molecular Weight[7]

The term "wetting" refers to how a material spreads and coats a surface. For example, if a water droplet is placed on a lotus leaf, the water will minimize the interaction with the leaf and produce a high contact angle. If a good wetting agent is added—either to the surface of the leaf or in the water solution, that same drop will spread out, coating the surface of the leaf. In turn making the leaf "wet," this is where the term wetting comes from. The spreading and wetting phenomenon is not only related to the air/liquid surface tension generated by the organosilicone surfactant but is also a function of the interfacial tension between the two

liquids that are typically present in an emulsion, along with the silicone surfactant. Figure 10.1.2[15] shows an illustration of Young's Equation and how the contact angle is defined.

Figure 10.1.2

As seen in Figure 10.1.2, the contact angle is the angle the water makes with the surface. In this illustration, a low contact angle ($\theta < 90°$) means the surface is hydrophilic. Large contact angles ($\theta > 90°$) lead to a surface that is hydrophobic.

Another measure of wetting is the time required for a standard skein of fiber, or of hair, to drop in an aqueous solution. This type of wetting time is called Draves Wetting (ASTM D2281). The lower-molecular-weight dimethicone copolyols have faster wetting times than their high-molecular-weight counterparts. The lower-molecular-weight polymers allow for more efficient packing efficiency. The materials with lower molecular weight are extremely effective at the higher concentration of 1.0 % w. Their wetting speeds are almost instantaneous—meaning the wetting is controlled by the rapid diffusion of the dimethicone copolyol to the air/water interface. An interesting finding is that wetting speed is slowly reduced as the molecular weight is increased. The slope of it increases once the molecular weight reaches a value of over 2,000. This implies that a rapid-wetting conditioner can be prepared by proper selection of organosilicone molecular weight. As the molecular weight of a polymer is increased, its ability to function in different capacities changes. This is due to hydrogen bonding and achieving lowest free energy. Figure 10.1.3 shows this.

Function of Dimethicone Copolyols vs. Molecular Weight	
Molecular Weight (Da)	**Function**
500	Wetting
2,500	Emulsification
10,000	Conditioning
50,000	Waterproofing

Figure 10.1.3

If the ratio of a to b is held constant, the molecular weight of the polymer controls its wetting properties. As shown in Figure 7.1.2, as molecular weight increases, the wetting ability decreases. Figure 10.1.4 shows the graph of molecular weight vs. wetting time.[18]

Draves Wetting[7]

Figure 10.1.4

b. Eye Irritation as a Function of Molecular Weight[7]

Not only do wetting properties depend upon molecular weight, but the molecular weight is also a controlling factor in eye irritation. Lower-molecular-weight polymers penetrate into the eye, causing more irritation to the eyes. As molecular weight increases, irritation decreases. However, there is a very definite molecular weight effect over which irritation becomes little or no problem. Figure 10.2.1.

Draize Primary Ocular Irritation Scale	
Moderately Irritating	25.1–50.0
Mildly Irritating	15.1–25.0
Minimally Irritating	2.6–15.0
Practically Non-Irritating	0.6–2.5
Non-Irritating	0.0–0.5

Figure 10.2.1

The data in Figure 10.2.1 was generated on a series of PEG 8 dimethicone copolymers with the same a to b ratio, by increasing the total number of a and b units. The eye irritation was run at 20% active and was evaluated over one and seven days.

Figure 10.2.2

c. Formulation Ingredient Interactions[1]

One of the most important factors facing the formulator of cosmetic products is how additives to formulations will interact with each other. This complication can include hydrophobic / hydrophilic interactions between ingredients, hydrogen

bonding between ingredients, insolubility or limited solubility of ingredients, and micellar interactions, just to name a few. This explains why there is a great deal of difficulty for the formulator to adapt raw material supplier data on the function of organosilicone products in a pure aqueous environment with data obtained in more complex systems. Figure 10.3.1 shows the effect of adding PEG-8 dimethicone to an aqueous solution of deionized water. The graph is quite ordinary and looks like what one might expect for a CMC. Notice, however, that the surface tension is significantly lower than for fatty surfactants (i.e., below 30 dynes/cm).

Figure 10.3.1

When the same PEG-8 dimethicone copolyol is added to a 1% solution of sodium lauryl sulfate, a completely different result is obtained. Figure 10.3.1 does not look like a CMC (critical micelle concentration) graph. Instead, it shows an interaction effect between the two surfactants as they compete for the surface at the air/water interface. While not a CMC graph in the classical sense, this graph and its shape are very enlightening as to the effectiveness of the silicone surfactant when added to the organic surfactant. Since there is no clear break point as is seen with the CMC graph, we created a new point so the effectiveness of the addition of a silicone surfactant to another surfactant vis-à-vis surface tension reduction can be determined. That term is designated the RF_{50} and it is described in Figure 10.3.3.

RF_{50} Definition[xiii]
RF_{50} = the concentration of silicone surfactant added to reduce the surface tension to 25 dynes/cm.

Figure 10.3.3

Figure 10.3.4 shows the results of addition of two different PEG-8 dimethicone molecules being added to a 1% solution of two different sulfated fatty surfactants.

Silicone Surfactant	Molecular Weight	Co-Surfactant	RF_{50} (%)
A-208	616.3	SLS	1.2
A-208	616.3	SLES-2	1.2
C-208	1,556.5	SLS	1.5
C-208	1,556.5	SLES-2	3.5

Figure 10.3.4

It is interesting to see from Figure 10.3.4 that when SLS is used as a co-surfactant, for the higher MW dimethicone copolyol the result has an RF_{50} of 1.5%, while the lower-molecular-weight dimethicone copolyol has an RF_{50} of 1.2%. This shows that the low-molecular-weight organosilicone copolymer is more efficient at lowering the surface tension when a co-surfactant is involved.

Upon comparing the RF_{50} in the samples containing SLES-2, the results are more dramatic. The RF_{50} for the low-molecular-weight dimethicone copolyol is 1.2, while the higher-molecular-weight copolyol is 3.5%. This is much more significant and is driven by the hydrogen bonding between the two moles of polyoxyalkylene on the SLES, making getting to the surface of the solution much harder for the larger C-208 molecule. The molecular weight of the silicone polymer has an impact upon the efficiency of the molecule to migrate to the interface and lower surface tension. The larger the molecule, the less efficient the molecule is in lowering surface tension.

How can these observations and behavior be applied when creating a cosmetic formulation?

1. It will be less efficient to use a higher-molecular-weight organosilicone copolyol to lower surface tension effectively in sodium laureth 2 sulfate systems (simply referred to as SLES-based systems). It would be more efficient to use a lower-molecular-weight dimethicone copolyol.
2. The evaluation of surface tension reduction in a formulation needs to be determined to maximize the effectiveness of the silicone in formulations. There is simply no other alternative.

Delivery of the silicone to the surface (interface) is a prerequisite to obtaining a consumer-perceivable result in formulations. The consumer can easily feel a difference in a formulation where there is a surface tension difference. As shown above, when organosilicone surfactants are added to others there is a foreseeable impact on efficacy. This efficacy can be measured by RF_{50}.

Another mostly neglected structural variable that can dramatically change RF_{50} is the solubility of the silicone being added. Insoluble materials cause formulation problems, and too-soluble materials result in the expensive silicone ingredient going down the drain. Products that form microemulsions (i.e., are thick and blue in color when added to water) are most efficient.

Consider the structure in Figure 10.3.5.

PEG-8 Dimethicone

Figure 10.3.5

As the ratio of a to b changes, the water solubility changes. This is because the "a" subscript (i.e., the number of repeating units of that species) is related to a group that lowers water solubility, while the "b" group represents the amount of the species that improves aqueous solubility. A polymer with an a:b ratio of 100:1 will be insoluble in water while one with an a:b ratio of 1:100 will be very water soluble. Somewhere in between these extremes, there will be a polymer that forms a microemulsion. It will be that polymer in the series that will offer the best effectiveness in solution. Using a wide range of a to b ratios, the optimal polymer can be determined that provides a desired microemulsion. Knowing the a:b ratio (D:D* ratio) provides a means to calculate the ratio at which a microemulsion can be formed. From the formula, shown in Figure 7.2.6, we can calculate the critical ratio needed to make a microemulsion.

Solubility in 10% H_2O			
D	**D***	**Calculated**	**Observed**
5	1.0	Insoluble	Insoluble
5	2.0	Soluble	Soluble
10	2.0	Insoluble	Insoluble
10	2.5	Micro	Micro
10	3.0	Soluble	Soluble
20	3.5	Insoluble	Insoluble
20	4.0	Micro	Micro
20	4.5	Soluble	Soluble
24	4.0	Insoluble	Insoluble
24	4.5	Micro	Micro
24	5.0	Soluble	Soluble
40	6.0	Insoluble	Insoluble
40	7.0	Micro	Micro
40	8.0	Soluble	Soluble

Figure 10.3.6

$\Omega = (0.17)x + 1$

Where Ω is the minimum number of D* units and x is the number of D units

It is always recommended that microemulsion-forming polymers can be used in cosmetic formulations, since these will be most effective at getting to the surface.

d. Water Tolerance[xiv]

In the previous section water-soluble silicones and silicone surfactants were discussed. In this section we introduce yet another important organosilicone-based phenomenon to formulating chemists. To begin our discussion we will have to first consider what happens when water is added to an anhydrous formulation. Most commonly, formulations will split or separate when water is added. Typically, in a nonsilicone, standard organic surfactant system this is because the addition of water changes the HLB of the system thereby decreasing the solubility of one of the components in the formulation. A useful new concept has emerged and it is called water tolerance. Basically, water tolerance is a measure of how much water can be added to a formulation before the formulation splits.

Dimethicone copolyols are interesting polymeric surfactants in that they can be utilized to increase the water tolerance of a formulation. To test how the dimethicone copolyol affects the formulation, the water tolerance of the formulation has to be determined. The determination of water tolerance is based upon the fact that dimethicone copolyols are soluble in anhydrous isopropanol, independently of their solubility in water. Water can be added to the isopropanol solution until a haze develops. This haze signifies the water tolerance of the solution, and the concentration of water tolerated by the formulation is called the "water tolerance." A common procedure for determining the water tolerance is described in Figure 10.4.1.

Water Tolerance Test
1. Dissolve 2.0 g of dimethicone copolyol in 100.0 g of isopropanol.
2. Slowly titrate in deionized water into the isopropanol solution.
3. Record the number of grams of water needed to produce the first haze.

Figure 10.4.1

Figure 10.4.1 shows the water tolerance of specific silicone compounds. As the D:D* ratio (a:b ratio), i.e., the number of D units (hydrophobic) compared to the number of water soluble groups (D*), increases, the materials become more water insoluble and the water tolerance drops. What is very interesting and warrants consideration is the fact that one mole of propylene oxide will increase water tolerance as much as four moles of ethylene oxide does.

Figure 10.4.2

e. Antiperspirant Release[17]

Along with the interesting wetting and water-tolerance phenomena we have presented in this chapter, dimethicone copolyols are of interest in a wide variety of applications. One of the more significant product categories is the use of dimethicone copolyol in antiperspirant applications. The copolyol contains PEO or PPO groups that are capable of coordination with different materials. This interaction between polyoxyethylene groups in dimethicone copoylols, while providing dryness in feel, inhibits the efficient release of the active from antiperspirant sticks. Several formulations were prepared and evaluated. The formulations are shown in Figure 10.5.1.

Antiperspirant Formulation		
Material	**Formulation**	
	A	**B**
Reach AZP-908	24.0	24.0
PEG-12 Dimethicone	-	2.5
PEG/PPG 8/8 Dimethicone	2.5	-
Cyclomethicone	30.0	30.0
Polydecane	9.0	9.0
PPG 14-butyl ether	9.0	9.0
Hydrogenated Castor Oil	2.5	2.5
PEG-8-Distearate	1.0	1.0
Stearyl Alcohol	18.0	18.0
Talc	3.0	3.0
Cab-o-sil-MS	0.5	0.5
Fragrance	0.5	0.5

Figure 10.5.1

The formulations shown in Figure 10.5.1 were evaluated and tested. The procedure and results are shown below.

A.P. Release Methodology

Reagents:
1. Silver Nitrate (0.05%N)
2. 10% nitric Acid

Apparatus:
1. Constant temperature water bath.
2. Lab stirrer with RPM reading
3. 250 ml beaker
4. Analytical Balance
5. Weighing dish
6. Spatula
7. Filter paper (Whatman # 4)
8. Funnel
9. Automatic Chloride titrator (Brinkman)
10. Magnetic Stirrer
11. Thermometer

Procedure:
1. Weigh 199 grams of DI water into a 250 ml beaker and heat to 37ºC
2. Place the beaker in a constant temperature water bath and mix well at 250 RPM with an overhead mixer.
3. Weigh 1.1 gram of antiperspirant stick by shaving wih a spatula from the surface of the stick
4. M ix for 30 and proceed to step 6.
5. Repeat steps 1-3 three more times only this time for 60, 120 and 240 minutes
6. Filter through filter paper and collect liquid for chloride titration.
7. Add 15 mo of 10% nitric acid and mix well.
8. Analyze for chloride ion using the auto titrator
9. Calculate % chloride

$$\frac{\text{\% Chloride titrated}}{\text{Theoretical \% chloride}} \times 100 = \text{\% Active}$$

The release of chloride ion is an indication of the effectiveness of the antiperspirant. Figure 10.5.2 shows the results.

Release Data				
Formulation	**30 min**	**60 min**	**120 min**	**240 min**
A PEG-8/PPG-8 Dimethicone	96.2 %	96.5 %	98.8 %	-
B PEG-12 Dimethicone	43.0 %	61.3 %	80.5 %	90.6 %

Figure 10.5.2

As seen in Figure 10.5.2, the introduction of poly (propylene oxide) groups into the polymer chain results in more efficient release.

f. Summary

As a class of materials, dimethicone copolyols offer the formulator the advantage of using aqueous solutions and introducing water into formulations that are typically anhydrous. However, if the dimethicone copolyol used is too water soluble in the formulation, it will be of little value to that formulation. If the expensive silicone compound stays in the water phase and ends up down the drain, it is ineffective. Alternatively, if the product is too insoluble, clear systems will not be obtained. The particular product needs to be matched to the formulation (not just to water) to ensure it ends up at the interface where silicone can perform its "magic."

4.2.3.19 ALKYL DIMETHICONE

Alkyl silicones are a class of amphilic silicones that contain within one molecule both a silicone-soluble group and an oil-soluble group. These materials are of interest to the personal care formulator for a number of reasons. They are very useful polymers because they are soluble in nonpolar solvents, they migrate to the surface between the oil and the substrate, they lower surface tension of oils, and they improve the spreadability of formulations on skin and hair.

It is well known that a fatty surfactant like sodium lauryl sulfate added to water will decrease the surface tension from 72 dynes/cm to as low as 30 dynes/cm. The same phenomenon occurs when an alkyl silicone is added into oils; with one notable exception, the oil will have an initial surface tension of 32 dynes/cm. Figure 11.0.1 shows the effect.

Figure 11.0.1[16]

As seen from Figure 11.0.1, the surface tension of soybean oil was decreased drastically from about 32 to about 22 dynes/cm. This surface tension reduction causes an increase in spreadability. This increase in spreadability makes the oil feel dryer (more silicone-like) and provides a more elegant feel on the skin. The reduction of surface tension in such oils is dependent upon the ability of the alkyl silicone to reach the liquid surface and orient itself properly. An effective silicone product must possess a balance between solubility and function. The alkyl silicone must be sufficiently soluble to provide clarity, yet sufficiently insoluble to migrate to the surface. The most efficient polymer for reducing the surface tension is the one that can provide the lowest surface tension at the lowest concentration.

a. Alkyl effects

Along with the ability to lower surface tension and increase the solubility of the silicone in oil, alkyl dimethicone copolymers can also change the physical properties of the materials that they are added to. By changing the alkyl group attached to the silicone backbone, a wide variety of products can be obtained. Attaching alkyl groups containing 16 or less carbons atoms in their alkyl chain will result in a liquid product at ambient temperature. Alkyl groups with 18 or more carbon atoms in their alkyl chain are solid at ambient temperatures. Adding alkyl dimethicone, with long carbon-pendant groups (≥ 18 carbons) to a liquid product will cause the material's melting point to increase. The opposite is true for a product that has a high melting point. In other words, adding alkyl dimethicone, with a small carbon-pendant groups (≤ 16 carbons), can drastically lower the melting point of the product and add liquidity.

b. Silicone-to-alkyl ratio effects

Alkyl dimethicone polymers not only have the ability to form solid and liquid products, they also have the ability to change the physical properties of the solid. By tuning, or changing, the silicone to alkyl ratio (changing the "a" to "b" ratio in the structure), the physical properties of the solid can range from a very brittle opaque solid (high alkyl) to a translucent wax (high silicone). Increasing the percentage of silicone will result in a softer wax with minimal effect upon melting point. This ability to control the tensile strength applies not only to the polymer in bulk but also when it is added into a product's formulation. The addition of a silicone with the correct silicone-to-alkyl ratio provides a formulation chemist the ability to "stiffen" or "soften" a solid.

c. Example: Cetyl Dimethicone

The structure of cetyl dimethicone is shown in Figure 11.3.1.

Cetyl Dimethicone

Properties	
Melt Point:	37°C
Solubility:	Esters, Triglycerides, & Other Oils

Figure 11.3.1

When cetyl dimethicone is added to oil-based formulations, cetyl dimethicone improves spread on the skin of that oil by lowering surface tension. Figure 11.3.2 shows the CMC curve of cetyl dimethicone in mineral and soybean oil.[16]

Figure 11.3.2

This results in the oil phase feeling more siliphilic (silicone-like), and adds a silicone- like feel. Cetyl dimethicone is added to sunscreen formulations since it increases spreadability on the skin surface and also tends to increase SPF values, because more uniform films of sunscreen actives are deposited.

d. Behenyl Dimethicone

The structure is shown in Figure 11.4.1.

Behenyl Dimethicone	
Properties	
Melt Point:	37°C
Solubility:	Esters, Triglycerides, & Other Oils

Figure 11.4.1

Alkyl silicones having high content of solid alkyl groups (50% or more of the polymer) will provide a translucent occlusive coating to the hair and skin. As the amount of silicone increases, the material becomes less soluble in the oil and the resulting wax is no longer occlusive. Figure 11.4.2[xv] shows this phenomenon.

10 % Behenyl Dimethicone in Olive Oil				
Olive Oil	**A**	**B**	**C**	**D**
-	20% Silicone 80% Alkyl	40% Silicone 60% Alkyl	60% Silicone 40% Alkyl	80% Silicone 20% Alkyl

Figure 11.4.2[18]

As seen in Figure 11.4.2, as the amount of silicone in the polymer is increased, the solubility in olive oil decreases. This leads to an opaque gel that melts upon the application of heat.

Another interesting phenomenon when it comes to alkyl silicones is the critical gelation concentration. As seen in our last example, 10% wt of behenyl dimethicone added to olive oil produced a solid product. If a lower concentration of alkyl silicone is added to an oil, will the oil be a liquid or a solid? To investigate this phenomenon, we studied the concentration at which a particular oil or silicone can be gelled and provide a nonflowing wax. The point where the oil or silicone stops

flowing is called the gel concentration. Alkyl dimethicone was added to 50-viscosity silicone fluid at varying concentrations. The resulting materials were evaluated for flow behavior. The results of this test are shown in Figure 11.4.3.[16]

Alkyl Silicone in 50-Viscosity Silicone Fluid

0%	10%	20%	30%	40%
Liquid	Liquid	Solid	Solid	Solid

Figure 11.4.3[16]

As seen in Figure 11.4.3, the critical gellation concentration (CGC) was between 10 and 20 wt %. It is important to note that the CGC will be different for every solvent and should be evaluated before the formulation is put together.

4.2.3.20 MULTI-DOMAIN ALKYL SILICONES

The previous section of this chapter has focused on alkyl silicone polymers. In this section, we will discuss a new class of alkyl silicone where there are at least two different alkyl groups covalently bonded to the same silicone backbone. This class of alkyl silicones contains at least two alkyl groups, one of which is solid at room temperature (C16 and above) and at least one of which is liquid at room temperature (C8 to C16). These alkyl silicones fall into a category called multi-domain silicones. A generic structure is shown in Figure 12.0.1.

Multi-Domain Alkyl Silicone

Figure 12.0.1

These multi-domain silicones have very interesting phase behavior. The different pendant groups can aggregate together and form pockets of solid and liquid in a highly organized structure. Figure 12.0.2 shows a representation of these highly organized structures.

Figure 12.0.2

In order to further study these multi-domain polymers, photomicroscopy was employed. These photomicrographs show the differences in the structure of the wax. Two different materials were evaluated. The first is the multi-domain product; the second is a blend having the same percentages of alkyl groups but on different polymers. This comparison will show if multi-domains act differently than two alkyl silicones blended together. The results are shown in Figure 12.0.3[16] and Figure 12.0.4.

Phase Contrast Microscopic Images	
Multi-Domain Polymer	Polymer Blend

Figure 12.0.3[16]

Polarized Light Microscopic Images	
Multi-Domain Polymer	Polymer Blend

Figure 12.0.4

Optical Images	
Multi-Domain Polymer	Polymer Blend

Figure 12.0.5

Physical Properties	Multi-Domain	Polymer Blend
Melting Point	34–38°C	56°C
Visual Appearance	Translucent Gel	Opaque Gel
Shear-Induced Flow	Yes	No

As seen from the polarized micrographs, multi-domain silicones are drastically different from a polymer blend of the same composition. In the multi-domain silicone, both alkyl chains are covalently bonded to the same silicone backbone. This restricts the degree of freedom of each alkyl chain

and drastically affects the properties of the solid. As two long alkyl chains (in the multi-domain silicone) come into contact with one another, they "stick together" and form a solid domain. As the long alkyl chains get incorporated into these solid domains, the small alkyl chains get excluded and start to form small liquid domains. Since both domains are attached to the same polymer backbone it is impossible for them to completely separate. This causes each solid and liquid domain to be confined into small regions and causes each solid domain to be surrounded by a liquid domain. The small domain size leads to many of the different properties of the solid, from scattering light (large domains scatter more light and are opaque to smaller domains that don't scatter much light and are translucent) to low melting point. The fact that the solid domain is surrounded by the liquid domain allows for the solid to flow under pressure. When a stress is applied to the solid, the solid domains can slide past one another more easily. This allows the solid to flow without breaking. In the polymer blend, the domains are not limited in size. Each domain can be very large size and this accounts for greater light-scattering ability (opaque solid) and the solid also becomes brittle. Since these multi-domains are highly organized compared to the blend approach, they can provide novel and specific properties needed for formulations. A comparison of a co-reacted product having liquid and solid domain (multi-domain) and a blend of alkyl silicones having the same ratio of alkyl groups is seen below.

a. Syneresis Improvement with Multi-Domain Silicones

Syneresis is a condition that exists in products that have raw materials with minimal solubility in each other. Over time, these formulations separate and generate an oil phase, which migrates to the surface. This phenomenon is called "sweating" or more accurately, syneresis. It is usually undesirable in cosmetic products and must be corrected to ensure stability.

Syneresis in pigment products such as lipsticks is difficult to correct since the presence of the pigment masks the underlying problem. If the same formulation—devoid of pigment—is melted, it will be observed that even when melted, the formulation will not be clear. Additionally, there will be a relatively wide melt range (4 or more degrees C). Both situations are indicative of incompatibility. Addition of the proper alkyl silicones to the formulation devoid of pigment will reveal that both problems are addressed. The melt point tightens to a much narrower range of 1–2 degrees and the clarity will improve. This will resolve or minimize the syneresis. The addition of multi-domain alkyl silicones will not only help resolve syneresis, but will provide a difference in cushion of the product and payoff of the color.

b. Summary

Alkyl silicones offer a cosmetic formulator a number of opportunities to alter the feel, consistency, and rheology of oil-based formulations. Alkyl silicones can also be used for the desirable attributes they provide in oil phases in the oils themselves, serums, emulsions, and any other form in which the oil is present. Adding structure to the oil phase will stabilize emulsions. Furthermore, alkyl silicones will provide (a) lower surface tension, (b) gelation, and (c) tactile changes.

4.2.3.21 ALKYL DIMETHICONE COPOLYOL

Alkyl dimethicone copolyols are the product of the co-hydrosilylation reaction of one or more alkyl group and one or more polyoxyalkylene group. This results in a silicone polymer backbone that has both a hydrophobic group and a hydrophilic group. Cosmetic products are named using what is called INCI **(International Nomenclature of Cosmetic Ingredients**) rules, which name these materials alkyl PEG / PPG dimethicone. The incorporation of both an oil-soluble and a water-soluble group onto the organosilicone backbone results in a series of compounds best known as emulsifiers. A typical compound has the structure shown in Table 13.0.1.

Table 13.0.1

Structure of Alkyl Dimethicone Copolyol

The INCI name for this material is lauryl PEG 8 dimethicone. Variation on the values of a and b has resulted in the development of a new series of emulsifiers that together make up an emulsifier kit that can be used to evaluate emulsifiers in

both regular (oil-in-water) and inverse (water-in-oil) emulsions. The composition is shown in Table 13.0.2.[7]

Table 13.0.2

Composition of Silicone Emulsifiers				
Material	**EO (%)**	**Alkyl (%)**	**3D HLB**	
			x	**y**
Lauryl PEG-8 Dimethicone A	**48**	**6**	**9.6**	**1.2**
Lauryl PEG-8 Dimethicone B	**39**	**13**	**7.8**	**2.6**
Lauryl PEG-8 Dimethicone C	**28**	**22**	**5.6**	**4.4**
Lauryl PEG-8 Dimethicone D	**16**	**32**	**3.2**	**6.4**

The ability to assess emulsion stability and make changes to improve it is a key concern to the formulator. Often the stability cannot be ascertained for weeks or longer using storage at low, ambient, and elevated temperature. The contraction of the development cycle experienced by the formulation chemist makes this approach problematic at best. A newer screening method has been developed using the range of emulsifiers listed above, which confers upon the formulator the ability to quickly ascertain basic information on emulsion stability in between three and 24 hours. This approach not only speeds up the formulation process but also allows for evaluation of both the inverse and regular emulsions in a shorter time period. The process begins with the evaluation of how the emulsifiers interact with the oil phase. Using the formulation 13.0.3, equal amounts of oil and water are evaluated, allowing for the creation of both a regular and invert emulsion using the four test emulsifiers. This basic work will allow for the first rapid evaluation.

Formulation 13.0.4[1]

Test Emulsion Formulation[1]	
Material	**Concentration (wt %)**
Water	47.0
Oil	47.0
Emulsifier	5.0
Salt	1.0

Procedure:

1. Place emulsifier or emulsifier blend into the oil phase.
2. Mix well, noting clarity.
3. Add salt to water phase.
4. Heat both phases to 50°C
5. Add water phase to oil phase and use mixer mix for 120 seconds.
6. Note appearance.

The above process is repeated with emulsifier blends depending upon the results of the first emulsion. The formulation is set up to allow for the evaluation of the ability of the emulsifiers to make regular (o/w) and inverse emulsions (w/o). The use of a common kitchen mixer further simplifies the process, as it will allow for rapid determination of emulsion stability. The technique is not a replacement for regular emulsification equipment in production but rather, is simple a tool for testing emulsion stability. Table 13.0.4 is used to expedite the evaluation of emulsions.

Sheer Mixer

Sheer apparatus for lab evaluation

Figure 13.0.5

Table 13.0.6

Lauryl PEG 8 Dimethicone in o/w Emulsion			
Time = 0			
J-208-212	**J-208-412**	**J-208-612**	**J-208-812**
Time = 3.0 h			
J-208-212	**J-208-412**	**J-208-612**	**J-208-812**
Time = 24.0 h			
J-208-412	**J-208-612**	**J-208-812**	

A clear separation can be seen in the J-208-212 sample in three hours. This trend continues and is much more dramatic in 24 hours. As seen above, some emulsions split after three hours and aren't compatible with this type of emulsion. This test produces very interesting results. More importantly, this test shows how slight modifications to the silicone polymer can produce an inverse emulsion, as in the case of the J-208-412 and standard emulsions, J-208-812. This shows the versatility of the silicone polymers; it is possible to rapidly modify the polymer to produce a good emulsifier for both inverse and regular emulsions.

4.2.3.22 GREENING WITH SILICONE

There has been a great deal of interest in "green chemistry." While the definition of "green" can be open to interpretation, the desirability to use sustainable raw materials in our products is clearly a goal.

But in addition to being made from sustainable raw materials, formulations need to meet their expectations. The goal therefore is obtaining formulations with the maximum content of sustainable raw materials, with highest performance, that are cost effective and aesthetically appealing—Ah, this is the holy grail. Clearly, a balanced approach is required and totally green is a destination; this is a journey not a one-step process.

The majority of consumers will always consider cost, performance, and impact on human health as the critical primary considerations and, in many instances, the deciding factor in consumer acceptance. However, this alone is not enough.

While the concept of green products is straightforward, the ability for the formulator and the consumer to quantify the greenness of a given shampoo or other consumer product is elusive. Given a proper understanding, the consumer and formulator can make better-informed and better-educated decisions about the best combination of green properties and formulation attributes for their products. In other words, the needs of the consumer, the needs of the environment, and conformation with regulatory guidelines can be intelligently determined. All too often, the determination of the greenness of a raw material or formulation is more an emotional than a scientific decision and requires either an all-or-nothing approach to environmental stewardship. Simply put, materials are either green or they are not. The consumer's demand for many formulation benefits cannot be achieved with all green ingredients; therefore, "non-green" products are required. The consumer then needs a systematic approach to develop a measurable metric for the level of greenness in a formulation and trade off some greenness for performance. This quest has resulted in the development of "Green Star Rating" defined in U.S. Patent Application **20090259409** system, or simply "GSR."

The Green Star Rating is calculated by taking the Green Star Value and multiplying it by the amount of actives in the product (% solids). To obtain the Green Star Rating for a formulation, simply add up the contributions by each of the raw materials. Once this number is known, the effect of replacing one ingredient in a formulation with a "greener" compound can be ascertained. Specifically, if a raw material used in a formulation at 20% by weight with a Green Star Rating of 1 is replaced with a product with a Green Star Rating of 7, the impact on the formulation is (7–1) times 0.20 or 1.2. This means that many more renewable resources are being used in the formulation and its consumption of this product will have a less negative impact on the environment. This approach allows the formulator to make greener products, with a higher Green Star Rating, and allows the consumer to choose these greener products.

The Green Star Rating is determined using the following steps:

(1) Determining the empirical formula for chemical compounds used to make formulated products;
(2) Determining which portions of the molecule are green;
(3) Determining the percentage by weight of the green portion of the molecule;
(4) Determining the green star value and optionally;
(5) Optimizing the formulation by selecting components with the greatest green star value.

Hair Glosser

Formulation 14.0.1

Material	**Concentration (% wt)**
Cyclomethicone and Dimethiconol	95.0
Argon Oil	5.0
Green Star Rating:	**0.5**

Formulation 14.0.2

Material	**Concentration (% wt)**
Olive Oil	80.0
Octyldodecyl Citrate Crosspolymer	15.0
Argon Oil	5.0
Green Star Rating:	**10.0**

Formulation 14.0.3

Material	Concentration (% wt)
Olive Oil	80.0
Octyldodecyl Citrate Crosspolymer	14.0
Argon Oil	5.0
Behenyl dimethicone / Vinyl Dimethicone Crosspolymer	1.0
Green Star Rating:	**9.9**

The above formulations were evaluated on hair tresses for softness, gloss, and spreadability on a scale of 1–5 (5 is best).

Table 14.0.4

Property	Formula 10.1	Formula 10.2	Formula 10.3
Softness	3	4	5
Gloss	3	4	4
Spreadability	4	3	5
Total	10	11	14
GSR	**0.5**	**10.0**	**9.9**

The analysis above would need to be evaluated to pick the product that is overall best for the market or markets. If the objective is an all-green product, then Formulation 10.2 would be the winner. If the market calls for strictly on performance and not on green, best overall product is desired Formulation 10.3.

a. Summary

While the term "green chemistry" might not be the best to describe this new approach to chemistry, it is a step in the right correct direction. What is clear from this is that a formulation with 99.99% renewable resources is better than one with 99.99% nonrenewable materials. The formulation of products for the personal care market requires consideration of many factors, including, but not limited to: maximum green content, highest performance, optimal cost effectiveness, and most esthetically appealing product. With that in mind, the incorporation of small amounts of an effective organosilicone into a cosmetic or personal care product to give that product optimal performance may be the future of silicone chemistry.

SILICONE ELASTOMER APPLICATIONS

By

John Gormley
Director of Regulatory Affairs /QA

GRANT INDUSTRIES
103 Main Avenue
Elmwood Park, NJ 07407 USA

ABSTRACT

Silicone elastomers are a broad class of cross-linked dimethicone polymers that form three-dimensional polymeric structures and provide a beneficial texture and appearance to cosmetics. They are generally formulated into products to enhance consumer appeal by yielding a preferred sensory profile, while functioning for example as anti-aging ingredients such as that of a line filler and soft-focus particle. They also can act as sebum absorbers to reduce excess oil on the surface of the skin and act as mattifying agents, which is just another way to say they make the skin less shiny. Further, these cross-linked dimethicone polymers are capable of delivering actives by acting as controlled-release polymers and can also reduce the oily texture of high-oil-content formulas. Several formula examples are provided to show how silicone elastomers may be co-formulated with common ingredients such as sun protection actives and pigments in order to provide elegant daily wear cosmetics or lotions.

Having described in great detail the varying structural types of silicone-based elastomers and gels in a previous section of this book; we come now to a description of their usefulness in cosmetic and personal care products.

4.2.3.21 SILICONE ELASTOMERS FOR IMPROVED CONSUMER ACCEPTANCE OF A PRODUCT: ACHIEVING THE "WOW" EFFECT

There is always opportunity to offer products that make people say "wow" (sensory elegance) while enhancing the delivery of actives that promote skin health, beauty, and the perception of ageless elegance. As described previously, silicone elastomers are a broad class of cross-linked dimethicone polymers that form a three-dimensional structure and can provide a sought-after texture and appearance to cosmetics. The key to achieving the optimal structure is to create an interstitial pore volume, defined by the cross-link density of the silicones. This elastic volume can be swollen (filled) with a solvent or even a small active material for obtaining enhanced delivery attributes. Depending on the chemistry and process to make them, silicone elastomers may be called silicone crosspolymers, dimethicone crosspolymers, dimethicone/vinyl dimethicone crosspolymers, or Polysilicone-11 (CTFA designation). Altogether, this class of cosmetic ingredients provides a wide range of elegant textures and promotes compatibility with other commodity ingredients. They are generally formulated into products to enhance consumer appeal by yielding a preferred sensory profile, while functioning as a line filler, sebum absorber, soft-focus particle, and mattifying agent. Higher-end cosmetic creams and lotions may contain a significant percentage of silicone elastomer, as this type of formulation helps create a positive consumer feedback loop that reinforces the performance and value associated with a brand. Silicone elastomers (in all their wide varieties) are available as loose powders, as swollen mixtures in cosmetic solvents, and as dispersions in water. The basic polymers can be further compounded into anhydrous and aqueous "formula bases" to help remove the need for later homogenization and/or to help take the guesswork out of the correct emulsifier blend required for stabilizing silicones in a formula.

The name "elastomer" is associated with this class of materials because the primary polymer shares many of the elastic qualities of rubbers, including medical-grade silicone rubber. One distinction we would point out is that the final size of the cosmetic-grade silicone elastomer is on the micron scale, typically on the order of 5–50 microns. This sizing property provides a small enough material to be

generally invisible on skin, but large enough (nano-free) to never be able to penetrate the dermis. This type of material is known for being ultra-mild, breathable, and nonocclusive. It can also be used to deliver soluble actives when the elastomer interstitial pore size is matched to the size of the active ingredient of choice.

A linear polymer like dimethicone is a versatile material that helps reduce drag, provide some silicone texture, and form a breathable protective barrier film on the skin. Unlike silicone elastomers, dimethicone is not promoted as a mattifying ingredient since it really does not absorb sebum and is actually glossy in appearance.

The main difference between the linear dimethicone and a cross-linked dimethicone elastomer is that when solvents are introduced into the product, linear polymers become soluble, whereas elastomers swell or expand, and do not lose their semi-spherical shape. This difference in behavior allows solvents, sebum, and actives to be transported in and out of the interstitial pore area. When volatile solvents are used in the formula, they disappear from the material upon dry-down and leave an invisible elastomeric sponge behind. This sponge is capable of soaking up all of the excess sebum produced by the skin to provide a desirable, continuous matte appearance throughout the day.

As described previously, the chemistry of forming an elastomer or crosspolymer can be extremely varied, but most commercially available elastomeric silicones share at least one common attribute in that an existing dimethicone polymer containing a reactive hydrogen "methicone" site is cross-linked with a terminal divinyl dimethicone or an organic diene to form rungs like a ladder across two or more polymers. The net result is a three-dimensional structure that is able to absorb or release solvents and actives as generalized in Figure 1.

Figure 1: Generalized dimethicone crosspolymer prepared with vinyldimethicone cross-links.

When optimized in production, this reaction is processed into a soft material that presents a unique "silky" texture that only silicone elastomers are able to provide. Each manufacturer has proprietary methods and recipes to create their exact type of product required. There is a wide choice available in terms of cross-linkers and divinyl compounds that commercially yield a nearly limitless variety of elastomers with different cosmetic attributes.

Less common varieties of silicone crosspolymers can also be formed by cross-linking pendant sulfur groups on dimethicone in the presence of catalysts like titanium dioxide, zinc oxide, or hydrogen peroxide, or by cross-linking polymethylsiloxanes (dimethicones) by a tin catalyst. Higher alkyl groups can be substituted for methyl groups in a wide variety of ways to promote compatibility with hydrocarbon solvents and alkyl esters. Likewise, ethoxy and/or propoxy (EO/PO) copolyol functional groups can be added for self-emulsifying properties.

4.2.3.22 COSMETIC ATTRIBUTES – TEXTURE AND OIL CONTROL (MATTIFYING)

Even small amounts of oil (sebum) on your skin can produce a shiny or uneven appearance. An overproduction of sebum results in oily skin or oily zones (combination skin) where the oil is more localized. The "T-zone," which is the facial area across the forehead and down the nose and chin, is a problem area that typically benefits from the use of oil-control products. Oil-control products are designed to counteract sebum production by soaking up oil and maintaining a soft, matte appearance.[1] An absorbent is a class of ingredients that can pick up and hold liquids. Small hard talc, minerals, and other polymers can act to absorb sebum on the surface. Among these ingredients, silicone polymers are exceedingly mild and safe on skin, they have no color or odor, they are highly oxidatively stable (even when heated), and they do not promote free radical formation under UV exposure. Moreover, consumers are able to discern the improvements in sensory properties and oil control provided by formulas containing silicone elastomers with mattifying properties, and this attribute set is directly linked to their popularity in cosmetics.

Sebum absorption, polymer swelling, and the pore volume (interstitial area) of an elastomer depend on the number (cross-link density) and polymer length of the dimethicone and divinyl dimethicone chains. A high cross-link density produces a hardened product that has less freedom to expand, even in the presence of a good solvent. Lightly cross-linked polymers create a flexible product with more solvent-absorbing capacity, but offers less refined texture. The perfect combination of polymer chain length and cross-link density provides ideal expansion, oil absorption, and a smooth texture on skin. If the combination is close, but not perfect, pilling may occur during rubbing as well as dry-out to give a visible powdery texture that is undesirable. A silicone elastomer with the INCI name Polysilicone-11 is a

highly refined combination of the above attributes that is offered in a wide variety of solvent combinations for tailoring the application.

Typical solvents combined with silicone elastomers are cyclomethicones (which have continued to receive safe-as-used opinions from recent Canadian CIR and EU-based SCCNNF reviews[2]), dimethicones, alkanes (dodecane and coconut alkanes), and other compatible emollients. Cyclopentasiloxane is the most widely used solvent, as it helps to loosen sebum and ultimately volatilizes off, thus exchanging cyclopentasiloxane (D5) for sebum in the elastomer space.[1] This solvent exchange leads to extended mattifying effects. Likewise, volatile and semi-volatile dimethicones can be used in place of cyclomethicones (along with actives, colorants, and sunscreens) to be used in elegant daily wear formulations as shown in the examples below.

4.2.3.23 EXAMPLE COSMETIC FORMULAS WITH SILICONE ELASTOMERS

	FORMULA	UV SHIELD/REPAIR BB CREAM, SPF~15	
Phase	**Ingredient**	**INCI**	**%**
A	GRANSIL DMG-3	Dimethicone & Polysilicone-11	10.000
	DIMETHICONE, 5CST	Dimethicone	8.000
	GRANSURF 67	PEG-10 Dimethicone	2.000
	GRANSURF 50C-HM	Dimethicone & PEG/PPG-18/18 Dimethicone	2.500
	GRANSIL 530	Dimethicone	1.000
	UV CUT TIO2-55-CG	Titanium Dioxide & Caprylic/Capric Triglyceride & Stearic Acid & Alumina & Polyhydroxystearic Acid	15.000
	PROTACHEM CTG	Caprylic/Capric Triglyceride	3.000
	EUXYL PE 9010	Phenoxyethanol & Ethylhexylglycerin	1.000
	BENTONE 38V	Disteardimonium Hectorite	1.000
B	SUNCROMA YELLOW IRON OXIDE	Iron Oxide	0.726
	SUNCROMA RED IRON OXIDE	Iron Oxide	0.218

	SUNCROMA BLACK IRON OXIDE	Iron Oxide	0.072
	RBTD-MS3	Titanium Dioxide (CI 77891) & Methicone	3.632
	SERICITE DNN	Mica	3.632
	DIMETHICONE, 5CST	Dimethicone	4.140
	GRANSURF 67	PEG-10 Dimethicone	1.380
C	DEIONIZED WATER	Water	30.700
	GLYCERINE	Glycerin	4.000
	BUTYLENE GLYCOL	Butylene Glycol	2.000
	GRANACTIVE 1518	Water & Polysorbate 20 & Pentapeptide-21 & Morus Alba Root Extract & Resveratrol & Scutellaria Lateriflora Extract & Hydrangea Arborescens Root Extract & Phenoxyethanol & Capryl Glycol & Potassium Sorbate & Hexylene Glycol	5.000
	SODIUM CHLORIDE	Sodium Chloride	1.000
		Total:	100.000

Procedure:

1. Combine Phase A in the main kettle and homogenize at 1000 to 1500 rpm until uniform.

2. Combine Phase B and run ball mill until the drawdown passes 10 micron on Hegman Gauge.

3. Combine Phase C in the support kettle and mix until the solids are dissolved.

4. Add Phase B into the main kettle while homogenizing and continue mixing for at least 20 minutes.

5. Add Phase C very slowly to the main kettle while homogenizing. At the end, increase to speed to 1500 to 2500 to finish the batch.

The wide variety of solvent options available in combination with silicone elastomers ultimately allows consumers to pick the cosmetic products best suited for their skin type. One typically applies these products before putting on the rest of your makeup, but many of them can be reapplied over makeup throughout the

day without having any detrimental effects. As we described earlier, talc and silicone powders are popular products for oil absorption and slip. The example formula below shows how a combination of silicone elastomer (Polysilicone-11) and silicone powder (polymethylsilsesquioxane) can be emulsified into a very smooth-feeling serum. This formula offers the flexibility of further designing in additional choices of oil-soluble and/or water-soluble actives (where applicable) without losing the premium texture profile.

	FORMULA	**SMOOTH W/S SERUM**	
Phase	**Ingredient**	**INCI**	**%**
A	GRANSIL DM-5	Dimethicone & Polysilicone-11	20.000
	DIMETHICONE, 5CST	Dimethicone	20.000
	JEECHEM ISP	Isopropyl Palmitate	5.000
	GRANSIL PSQ	Polymethylsilsesquioxane	5.000
	GRANSURF 67	PEG-10 Dimethicone	1.500
	GRANSURF 50C-HM	Dimethicone & PEG/PPG-18/18 Dimethicone	0.500
	PROTASORB O-80	Polysorbate 80	0.700
	VITAMIN E ACETATE	Tocopheryl Acetate	0.200
	EUXYL PE 9010	Phenoxyethanol & Ethylhexylglycerin	0.600
B	DEIONIZED WATER	Water	35.500
	BUTYLENE GLYCOL	Butylene Glycol	10.000
	CARBOPOL ULTREZ 10 POLYMER	Carbomer	0.600
	SODIUM HYDROXIDE, 25% AQ SOLUTION	Water & Sodium Hydroxide	0.400
		Total:	100.000

Procedure:

1. Combine Phase A in the main kettle and mix until uniform.
2. Combine Phase B in the support kettle and mix until no lumps.
3. Add Phase B into A while mixing and mix until uniform.

4.2.3.24 SUMMARY

Silicone elastomers are three-dimensional polymeric structures that can be combined in a delivery solvent of choice to provide premium texture- and oil-control attributes that are recognized by consumers in top-selling cosmetics around the globe. They act as line fillers, soft-focus particles, sebum absorbers, mattifying agents, texture modifiers, and controlled-release polymers. The can be formulated in most common types of cosmetic creams and lotions, including pigmented cosmetics, and originally impacted the industry in oil-control foundations and other products where enhanced mattifying and sensory properties are highly desired. In many respects, silicone elastomers are able to further enhance a basic formula such that it is more able to meet a higher level of consumer acceptance in order to reinforce or couple together brand performance and brand loyalty.

ABSTRACT

It is well known that whitening products represent a very large category for skin care in Asia , especially in Japan where beauty products feature the function of Bihaku (beautiful white). Eastern women tend to have yellowish skin, so whitening in Asia is equivalent to anti-wrinkles for Caucasians. A light complexion was considered as a sign of elegance among nobles, educated people, and members of the higher classes in China since ancient times. As far back as the ancient Qin Dynasty (221–205 BCE), there have been records on Chinese medicines that have beauty functions. For example, there were records about using Bai Zhi (*Angelica dahurica*) in facial cream during this period. In the later Tang Dynasty skin care grew in popularity.

Like the women in ancient China, women in ancient Japan were also concerned about maintaining a white skin. No wonder that the faces of Japanese women are white in the drawings and paintings. More recently, in the last half-century, there appeared the first whitening powders in Japan and 20 years ago such products became a real boom. Along with this evolution came some regulation such as Quasi-Drug in Japan but also more sophisticated mechanism-based products beyond the classic anti-tyrosinase activity. This chapter looks at the evolution of the approach to whitening in the last 50 years and then explains the mechanism of action of the different active families and specific ingredients within those families. It also covers lightening of dark spots and moves from the basic molecules through more and more complex molecular ingredients and finally to modalities and possibilities based upon molecular biological approaches.

4.2.4.1 HISTORIC EVOLUTION OF WHITENING PRODUCTS IN JAPAN

In this chapter we present a unique view of the evolution of the category of skin whitening from the point of view of company and product introductions during each decade beginning with the 1960s.

In the 1960s, the first whitening powders appeared in Japan, for example, Soie de Reine Beauty C powder by Kanebo in 1966. The product contained an oil-soluble form of vitamin C and the goal was to provide a safe alternative to the bleaching action of hydrogen peroxide.

In the 1970s, the first whitening product series appeared with the introduction of Real Beauty (Kanebo) and Natural Shine (Albion) in 1971, and Freshure (Shiseido) in 1976.

In the 1980s, new lightening ingredients were developed and used in Lumiera (Pola) in 1980; Faircrea (Kanebo) in 1984 and in 1985 in UV White (Shiseido) and Sekkisei (Kose). This is also the time where the product form changed from a powder to an essence introduced by Estée Lauder (Swiss Whitening) in 1986, Kose (Sure White) in 1988—the year when Sansho Seiyaku obtained regulatory approval by the Japanese Ministry of Health, Labour, and Welfare (MHLW) to use kojic acid as quasi-drug (a short list of regulated actives used by skin care companies to use the claim "whitening")—and Kanebo in 1989 (Kanebo Blanchir). An essence corresponds to a serum in occidental countries: a water-based thin emulsion.

In the 1990s the skin-whitening category began to boom and extend its reach to the mass market as younger customers were targeted. Shiseido launched Whitess Essence (with arbutin), Kanebo launched Freshel White C (with "penetrating" vitamin C), and Kao launched Shokubutsu (with vitamin C as well). Closer to the

year 2000 the lines were again altered to new forms of products such as wipe-off lotion-type and soap-type products for cleansing, which performed by removing old keratinocytes.

After creating new type of products in the beginning of the 21st century, the trend has been to create more exclusive quasi-drug (QD) actives for lightening skin. This approach was accelerated in 2001 due to the BSE (Bovine Spongiform Encephalopathy) issue. The largest companies: Kose, Lever, Pola formulated out the bovine placenta due to this "mad cow disease." Shortly after Kojic acid was introduced as a QD in 1988. During that period this ingredient fell into disrepute due to alleged safety issues concerning possible carcinogenic effects (not confirmed since then). In view of this setback, most companies were condemned or limited to use vitamin C derivatives, with tyrosinase inhibition as the targeted activity. At present, the cosmetic industry is looking for exclusive ingredients from green and sustainable sources (preferably plants) that have a novel mechanism for skin whitening. Thus, there is a significant opportunity for ingredient seekers and formulators of novel, safe skin-whitening products that tie into the exploding demand by consumers for green and sustainable resources.

4.2.4.2 WHAT IS A WHITENING QUASI-DRUG?

It is not possible to talk about skin whitening without explaining what is the meaning of a whitening quasi-drug in Japan. A quasi-drug (QD) refers to the food, cosmetic, and drug standard regulated by the Japanese Ministry of Health, Labor, and Welfare (MHLW) under the Pharmaceutical Affairs Law. JSQI (Japanese Standard of Quasi-Drug Ingredients) and QD JSQI are the official standards set by the Japanese government for ingredients to be incorporated into final QD products, and labeled QD to advertise that the product is a government-approved medicated quasi-drug. This QD status has become a powerful marketing tool for many Japanese and foreign firms in the Japanese market. Obtaining QD status requires time and monetary investment, thorough documentation, and rigorous testing of safety and efficacy, all of which is regulated and approved by the MHLW. The efficacy of a QD is typically milder than that of a pharmaceutical drug, but has been proven effective in a specific claim category as either an excipient (additive) or an active at a specific dosage.

For skin whitening, this category in Japan is created for functional actives that will prevent hyperpigmentation or improve hyperpigmentary disorders. Most of the time the whitening products target an enzyme called tyrosinase. Tyrosinase is an enzyme needed for the production of melanin.

The following is a list of whitening QD in Japan in order of approval (from earliest to most recent) and it includes a description of their mode of action:

Bovine placenta:

This is a QD active that has been very popular and long used along with the use of vitamin C and its derivatives. The main source of placental extract was bovine, but it could also come from porcine origin, which has been recently used to replace the bovine due to the BSE issue. BSE was thought to be transmitted to human beings. The form of this disease in humans is the Creutzfeldt Jakob Disease, which killed numerous humans in the UK. Hatae et al. (1) and Ito (2) proposed, in the *Fragrance Journal of Japan*, the mode of action of placental extract as being an increased cell turnover to remove the melanin from the upper layers of the skin, or the role of high concentrations of minerals and amino acids, to reduce melanin synthesis.

Vitamin C (Ascorbic acid) derivatives:

Vitamin C and its derivatives are by far the most popular skin-whitening ingredients in use in Japan. Ascorbic acid and its derivatives are antioxidants, and as such they can block, for example, the conversion of DOPA to DOPAquinone; and from DOPAquinone, the melanin synthesis pathways can be blocked since the reaction pathway diverges to produce either eumelanin or pheomelanin (3). Most vitamin C derivatives approved as QD can be used as such by all customers. Some companies have had to obtain regulatory approval for the benefit of others! Takeda obtained the QD status for magnesium-ascorbic acid 2-phosphate in 1988 (use level must be 3%), and Shiseido obtained the QD status for L-ascorbic 2-glucoside in 1994 (use level must be 2%). Much later on, Nikko chemical, a supplier, obtained the QD status for use of tetra-isopalmitoyl ascorbic acid in 2007 (use level must be 3%). This oil-soluble form of vitamin C is easier to use and prevents UV-induced skin pigmentation through its antioxidative properties (4). The first company to introduce a QD product featuring this form was Green Coop in the QD line *Shion.*

Ascorbic acid

Tetra-isopalmitoyl ascorbic acid

Other forms of vitamin C: vitamin C-ethyl, L-ascorbic acid2-phosphate, etc, . . . are on the market but not necessary as QD.

Kojic acid:

The hydroxylation of L-tyrosine to L-DOPA is catalyzed by the action of the copper-containing glycoprotein tyrosinase enzymes located in the melanocyte's melanosome. Molecules chelating copper atoms can reduce the activity of the tyrosinase, and as a result, the melanin synthesis. This is how kojic acid functions as a skin whitener (5), and Shansho Seiyaku Co., Ltd obtained the whitening QD status in 1988.

Kojic acid

Kojic is a QD at the use level of 1%; Mishima et al. evaluated the molecule in clinical tests to treat freckles, age spots, and post-inflammatory hyperpigmentation (6). Due to some concern about the potential carcinogenic effect, the MHLW (Ministry of Heath, Labour, and Welfare) started in March 2003 to discourage companies to use Kojic acid. Although they somewhat came back on their decision, most companies remain hesitant to resume its use and prefer to consider alternatives.

Arbutin:

Arbutin was submitted by Shiseido to the MHLW and successfully obtained QD status in 1989 at the use level of 3%. Arbutin is found in the leaves of cowberry and is a derivative of hydroquinone.

Arbutin Cowberry

According to K. Maeda and M. Fukuda, arbutin is a naturally occurring beta-D-glucopyranoside of hydroquinone and is effective in the topical treatment of various cutaneous hyperpigmentations characterized by hyperactive melanocyte function. They report that arbutin inhibits the tyrosinase activity in cultured human melanocytes at non-cytotoxic concentrations. Melanin production is inhibited significantly by arbutin, as determined by measuring eumelanin radicals with an electron spin resonance spectrometer. The study of the kinetics and mechanism for inhibition of tyrosinase confirms the reversibility of arbutin as a competitive inhibitor of this enzyme. The utilization of L-tyrosine or L-dopa as the substrate suggests a mechanism involving competition with arbutin for the L-tyrosine binding site at the active site of tyrosinase. These results suggest that the depigmenting mechanism of arbutin in humans involves inhibition of melanosomal tyrosinase activity, rather than suppression of the expression and synthesis of tyrosinase.

Ellagic acid:

Lion applied for ellagic acid, a polyphenol, for whitening QD application at 0.5%. Approval was granted in 1996.

Ellagic acid

The discovery of ellagic acid was made by the chemist M. Chevreul in oak galls and more precisely studied by M. Braconnot in 1831. Ellagic acid is found in oak species like *Quercus alba* and *Quercus robur*. The green alga *Myriophyllum spicatum* produces ellagic acid; so too does the medicinal mushroom *Phellinus linteus*. However, the highest levels of ellagic acid are found in blackberries, cranberries, pecans, pomegranates, raspberries, strawberries, walnuts, wolfberries, and grapes. Considering the growing popularity of these fruits and nuts as sources for green and sustainable cosmetic actives, ellagic acid may have considerable room for growth in the skin-whitening area.

The mode of action is again (like kojic acid) copper chelation.

Chamomilla extract:

Kao, in 1998, obtained the QD status at 0.5% for this anti-inflammatory. This is quite unusual, as there is only one plant extract approved as QD so far and the mechanism does not involve tyrosinase. In the proposed mechanism of action for

chamomilla extract, cells communicate with each other and, once activated by UVB, the keratinocytes produce alpha-MSH and endotheline, which will bind to specific receptors in the *stratum corneum* and activate the melanocytes. Chamomille extract acts as an antagonist of this receptor and therefore reduces the "call" for melanin production.

Rucinol (4-n-Butylresorcinol):

Pola obtained a QD status for Rucinol at 0.3% in 1998. 4-n-butylresorcinol, is a resorcinol derivative that has an inhibitory effect on both tyrosinase and tyrosinase-related protein-1 and -2, and is featured in BA Grand Luxe or Whitissimo White Shot Spots, clear products of Pola as examples.

4-n-butylresorcinol

Linoleic acid:

Linoleic acid

Linoleic acid (LA) is an unsaturated omega-6 fatty acid called 18:2(n-6). Chemically, linoleic acid is a carboxylic acid with an 18-carbon chain and two "cis" double bonds; the first double bond is located at the sixth carbon from the omega end. This fatty acid can be obtained from hydrolysis of vegetals (such as safflower, evening primrose, or kukui seed oils). Linoleic acid (omega-6) is located in the cell membranes and can therefore decrease the tyrosinase level and accelerate tyrosinase degradation. This results in less melanin being produced, and an accompanying whitening effect on the skin.

Sunstar obtained the QD status for Linoleic acid at 0.1% in 2001.

Tranexamic acid:

Tranexamic acid

Tranexamic acid is a drug used to treat melasma. It is proven to inhibit UV-induced hyperpigmentation and melanocyte activity (lightening skin). This is especially true in people with melisma, or dark spots, where the pigment-suppressing abilities of tranxemic acid works best on localized areas of irregular melanin distribution. Tranexamic acid prevents the binding of plasminogen (originating from endothelial cells), to keratinocytes, which is thought to be a possible mechanism for melasma treatment.

This material is featured in Shiseido's Haku Melanofocus, and Shiseido is the company who obtained QD status for tranexamic acid in 2002.

4-Methoxy potassium salicylate (4 MSK):

The following year, in 2003, Shiseido obtained one more exclusive QD approval with 4 MSK; the mode of action is tyrosinase inhibition, and this whitening ingredient is featured in Clé de Peau la Crème manufactured by Shiseido.

4- MSK

Adenosine monophosphate disodium salt:

This active is QD when used at 3% and the status was obtained by Otsuka Pharmaceuticals Co. in 2004. This AMP salt acts as a fuel to the cells. They therefore produce more energy and, as a result, the epidermal turnover is increased and the cells containing melanin will exfoliate faster. This reduces the melanin content in the skin.

Adenosine monophosphate disodium salt

Dipropyl-biphenyl-2,2'-diol (Magnolignan):

This compound belongs to the family of polyphenols; it looks like the magnolol of magnolia. This active was approved for QD at 0.5% and was submitted for QD approval by Kanebo in 2005.

Magnolignan retards or slows down the maturation of tyrosinase.

4-HPB: 4-(4-Hydroxyphenyl)-2-butanol:

This active is a competitive inhibitor of tyrosinase. It can be found in white birch and Nikko's maple extract. The material is also known as rhododendrol.

4-(4-Hydroxyphenyl)-2-butanol

Kanebo, again, obtained approval for this molecule as QD in 2007.

Tranexamic acid cetyl ester hydrochloride:

Partnering with Nikko chemical, Chanel was the first non-Japanese company to gain approval for a new whitening molecule in 2009.

The mode of action is similar to the tranexamic acid used by Shiseido.

This ingredient is the most recent approval in Japan.

From a review of the information presented previously it is obvious there has been an accretion of approvals for ingredients that lighten skin. The year 2007 was special, as two molecules got approved! It is anticipated that the approved list will grow longer in the coming years, as this category is very important in Japan and Asia in general.

4.2.4.3 WHAT ARE THE QUASI-DRUG ADDITIVES?

Whitening is not just quasi-drug, there are also QD additives that are important to create a bouquet, which means a multifaceted approach to treat the question of whitening at different levels and a multifunctional approach in treating skin pigmentation. This is illustrated in the following schematic, which also summarizes

the various mechanisms of action and discusses the different types of strategy to reduce melanin synthesis, distribution, etc.

a. - In the melanocytes

Tyrosinase

Tyrosinase has been an early target for the whitening products. In molecular biology, tyrosinase is mainly involved in two distinct reactions of melanin synthesis; firstly, the hydroxylation of a monophenol and secondly, the conversion of an o-diphenol to the corresponding o-quinone. o-Quinone undergoes several reactions to eventually form melanin. Tyrosinase is a copper-containing enzyme present in the skin that catalyzes the production of melanin from tyrosine by oxidation.

As oxidation is a key to effective whitening, strong antioxidants are candidates to inhibit tyrosinase activity, and this is one of the functions of ascorbic acid derivatives. However, plant extracts are also used for their antioxidant properties, especially licorice root extracts as they contain glabridin, a strong antioxidant molecule:

Many cosmetic products in Asia contain licorice extracts for whitening.

Another molecule that has antioxidant properties is an amino acid called ergothioneine:

Ergothioneine

This molecule is a copper chelator and tyrosinase is copper-dependant. As a result, ergothioneine is an interesting molecule for achieving skin whitening, along with ellagic acid and kojic acid.

Arbutin and 4 MSK are examples of actives with competitive inhibition to tyrosinase.

Yet another strategy is to inhibit tyrosinase maturation or tyrosinase synthesis; in addition to magnolignan one can consider a zinc glycine complex:

This molecule was tested at 1% in an *in vivo* study and showed very good whitening effects in two weeks. Not only does this complex reduce the synthesis of tyrosinase but it also induces the synthesis of an antioxidant protein, metallothionein, a rich peptide with copper-chelating properties.

The most recent approach is to consider an action on MITF (microphthalmia-associated transcription factor) and to down-regulate this gene so the tyrosinase is not activated.

MITF is the transcription factor for tyrosinase (TYR) and tyrosinase-related protein 1 (TYRP1), which plays a key role in melanocyte development. MTIF binds to a symmetrical DNA sequence (E-boxes) (5'-CACGTG-3') found in the tyrosinase promoter.

MITF down-regulation can be achieved with a water extract of an alga called *Dictyopteris membranacae*.

melanosomes

This extract also down-regulates OA1, the gene regulating the number and size of melanosomes as well as MART1, the gene responsible for the maturation of

melanosomes and MLPH, the gene responsible for the migration of melanosome. Tested at 3% *in vivo* on Asian skin, the reduction of skin pigmentation was as high as 36% in three months.

b. - In the keratinocyte

Here the strategy is to limit the communication between the keratinocytes and the melanocytes. UV stimulates keratinocytes (and can break their DNA); therefore keratinocytes look for protection, they "ask" the melanocyte to produce melanin to be used as a "cap" for the next time keratinocytes are exposed to UV. The melanin will be carried in the melanosome to the "fingers" of the melanocytes, the dendrites, and given back to the keratinocytes.

The way keratinocytes signal their need for melanin is through alpha MSH messenger and endothelin messenger. These messengers find receptors on the membrane of the melanocyte and trigger the making of melanin. Undecylenoyl phenylalanine is a molecule that will act as alpha-MSH antagonist—no stimulation of the melanocyte eventually translates into less melanin production and a lightening action in the same way, but this time by preventing the endothelin adhesion. Ascophyllum nodosum extract is an algae extract that can block endothelin adhesion to the membrane of the melanocyte. *In vivo* study has confirmed the whitening effect of this active.

There is also another new target: POMC for achieving skin lightening. POMC is activated by the cytokines released by the keratinocytes under UV. Once POMC is activated, alpha MSH and endothelin are released. The down-regulation of POMC will stop the communication between keratinocyte and melanocyte.

c. - In the nerves—a new approach to the reduction of dark spots

As if all these interesting biochemical approaches are not enough to stimulate new ideas for skin whitening products, Codif international discovered that nerves also stimulate the melanocytes and increase the dendricity via a peptide called Substance P. Substance P is well known to be present in areas that are exhibiting pain. In this approach to skin whitening, the concept is called neurowhitening.

An extract of *Pancratum maritimum* (white sea lily or sea daffodil) can down-regulate POMC and reduce the stimulation from keratinocyte but moreover it can decrease the number of Substance P receptors. In other words, this extract prevents the stimulation of melanocytes from the nerves. Substance P receptors, once activated, increase the number of dendrites in the melanocytes. The dendrites are like these arms that the melanocytes use to distribute the melanin to the surrounding keratinocytes; it is reported that one melanocyte can reach out up to fifty keratinocytes:

Skin structure: far-reaching dendrites of melanocytes

Limiting the number of dendrites is especially efficient on age spots when used at 1.5% in three months.

Skin pigmentation is a complex issue and multi-tiered problem. There are various options upstream via limitation of melanocyte activation. There is yet another road to explore: the melanin is produced, wrapped up in melanosome, and sent to the dendrite—ready to be delivered. Here an enzyme is critical: PAR-2. If PAR-2 is blocked, the melanin will not be transferred.

The goal here is to seal off the melanin transfer.

Artemisia capillaris works very well as it is a PAR-2 inhibitor, and as a result it reduces melanin transfer from melanocytes to keratinocytes. Genomic tests were performed to confirm that Artemisia inhibits PAR-2.

Artemisia is a good addition to a multifunctional bouquet of actives that are needed to achieve a whitening effect in a cosmetic formula.

Tests have been performed at different levels, first of all in cell culture and pseudo melanin. Where Artemisia is used to reduce melanin transfer into the keratinocytes, there is less fluorescence. As seen hereafter:

Control (no Artemisia)

With 0.67% Artemisia (melanin inhibition is visible)

Further tests were run on skin models with UV applied. Melanin is still produced, but where Artemisia is used the melanin does not migrate to the surface, as seen hereafter:

Control (no Artemisia—melanin migration) 500 µg/ml Artemisia (limited migration; melanin stays at the bottom)

The same test was performed on the skin, and there was no tanning response when Artemisia was used at 2%, three times a day for three weeks. Tests were performed by Maruzen Pharmaceuticals in Japan.

d. - For the corneocytes

The last cells to target are at the very surface of the skin: the corneocytes. The goal here is to accelerate the epidermal turnover and with the desquamation the melanin will go away. To do so, varying chemical exfoliators are usually used: lactic acid, retinol derivative, and retinol-like glucosamine derivatives.

Another elegant approach to skin whitening is to increase the expression of the protein of desquamation, a group of serine proteases called kallikrein, which are capable of cleaving peptide bonds in proteins. The names of these human desquamation enzymes are KLK5 (*stratum corneum* tryptic enzyme) or KLK7 (*stratum corneum* chymotryptic enzyme), and certain marine exopolysaccharides are increasing these enzyme expressions.

Chemical exfoliation or enzymatic desquamation could also be combined with an active working at the melanocyte and/or keratinocyte level to enhance skin-whitening activity.

CONCLUSION

Whitening or skin lightening is a very important category in skin care and is taken very seriously in Asia, as this is one of the most important signs of aging there. For almost 50 years now the category of Quasi-Drug has been used to allow the safest and most efficient active, but for many years the choice was very limited to placenta, ascorbic acid derivatives, and kojic acid. In the last ten years there have been are six new molecules approved for QD application, but each is exclusive and limited by the company that applied for the ingredient patent. As the

process takes minimum of five years and can cost up to 5 million dollars, the bar to achieving success is very high. In the coming years new molecules are likely to be approved—of different categories: peptides, polysaccharides—and with new targets. It will remain a vibrant category.

ABSTRACT

What are algae? Something greenish-brownish, slimy, smelly, and attached to the rocks when the tide is low . . . slippery if you walk on it and after all, not that clean. This was yesterday's perception.

We are far removed from this perception nowadays when we think about the ingredient space occupied by the Marine Ingredients for Cosmetics category. Today, in cosmetics and personal care ingredients, one can chose from active fractions of large algae, polysaccharides from planktonic origin, or actives from plants from the coasts of many landmasses around the world. There are numerous ingredients available from marine origin, and they support many of the desirable claims consumers want to see when they buy their cosmetic and personal care products. In this chapter, we present an overview of marine ingredients and point out their value to the cosmetic and personal care formulator.

4.2.5.1 MARINE SOURCES OF ALGAE

a. What is an alga?

IN THE BEGINNING . . . it is believed that there were only bacteria on earth. Some of them evolved and had chlorophylian pigments; thus, the first algae were born. They could use the energy of the sun via photosynthesis to produce oxygen (O_2). They were major participants in the production of oxygen surrounding our planet—without algae, life would not have evolved as we know it today. Prehistoric evidence of the presence of the earliest algae is found in the fossils of stromatolites (Figure 1) [1]. These coral-like structures were created by the precipitation of sediments of cyanophycae—also known as the blue algae named *Phormidium*.

There are more than 25,000 kind of algae—there is more difference between a brown alga and a green alga than between the same green alga and a tree in the forest. Blue algae are close in structure to red algae (*Rhodophycae*), which are close to that of brown algae (*Pheophycae*) [2].

Algae are usually in water (but not always). They are different from other plants, as they do not bloom, they have no roots, no stem, and no leaves. All algae have in common a green pigment that provides the chlorophyll and therefore their ability for photosynthesis: (Figure 2) [3] [4].

Figure 1: Stromatolites

Figure 2

The two major categories of algae are: unicellular and microscopic. The latter type comprises an important part of the plankton and macroalgae. Examples of microalgae are: *Anacystis*, *Phormidium* (Figure 3), *Spirulina* . . . and their size can be as small as fraction of a millimeter.

Figure 3: Phormidium

Example of macroalgae are: *Laminaria*, *Palmaria*, *Fucus*, *Chondrus* (Figure 4) . . . and these types can be as long as 40 meters.

Figure 4: Chondrus

Blue algae molecules are used for cosmetic applications: enzymes, such as photolyase, and various types of exopolysaccharide. Macroalgae are rich in polysaccharides, which can be hydrolyzed into bioactive oligosaccharides. This important process will be discussed further later in this chapter.

b. Plants from the shore

The climate condition and soil composition by the shore are not optimal for plants to grow in view of the variation of climatic conditions and the composition of the soil. The plants growing in these areas develop a resistance to high salinity in the face of their repetitive exposure to the tides, and they have developed a resistance to dryness as well [5] [6]. Their adaptive response of the algae to the harsh environment led to production of defensive capabilities and protective secondary metabolites that may be beneficial to skin care applications and offer a significant opportunity for further exploration beyond the encouraging results and products available at this writing.

Figure 5: Salicornia

Examples of coastal plant: Salicornia (Figure 5) and Rock Samphire (Figure 6).

Figure 6: Rock Samphire

c. Other resources from marine origins

Minerals are in fashion in cosmetics, and the water of the ocean is a balanced cocktail of trace elements and minerals (more than 63 elements of the periodic chart have been identified). These minerals can be supplied as salts, or in the form of water including Hawaiian deep seawater, and various waters from the lagoons of Polynesia and the Dead Sea of Israel.

Figure 7: Lithothamnium

Microdermabrasion is also an important field where sea minerals provide an alternative to chemical polyethylene beads. Such materials are opportunities for formulators to investigate the white sands of Bora Bora, the black volcanic sands of Tahiti . . . or back to the algae powders of yellow or blue lithothamnium.

Lithothamnium (Figure 7) can be crushed to different sizes for milder face care or harsher foot care.

4.2.5.2 EXAMPLES OF THE USE OF MACROALGAE IN COSMETICS

a. Moisturization

Macroalgae produce polysaccharides [7]; these large polymers of sugar are in the "skin" of the algae. There is an amazingly striking similarity observed when comparing a cross-section of an alga (Figure 8) with the histology of human skin (Figure 9).-

The polysaccharide polymers present in the algae can retain a good level of moisturization—a result of repetitive exposure to low tides and the accompanying low-moisture environment.

Figure 8: alga skin

Figure 9: human skin

It is interesting to combine the contained polysaccharide polymers from microalgae with amino acids from chlorella and sea minerals from plankton, versus a placebo. With daily application, there is a cumulative, beneficial effect in enhanced moisturization (Figure 10). The combination of amino acids from microalgae with sea minerals strengthens the NMF level to produce an immediate hydration effect. It is observed that with high-molecular-weight marine polysaccharides a second skin forms on the epidermal surface to reduce water loss.

Figure 10: hydration effect of a combination of microalga AA, sea salts, and macroalga polysaccharide

b. Slimming

Marine ingredients can be used for sculpting the body. cAMP is key for activation of the lipase, which will initiate lipolysis. However, various factors limit the expression of cAMP. These include the presence of phosphodiesterase neuropeptide Y binding on its receptor and adrenaline binding to its alpha 3 receptor. Extracts of *Laminaria digitata* can inhibit all these negative factors and favor lipolysis. Figure 11 illustrates this fat-burning effect: pictures 11a and 11b show adipocytes with their fatty content in red. Treatment with *Laminaria digitata* extracts (11b) results in a reduction in the size of adipocyte and elimination of fatty acids. Another brown algae called *Sphacelaria scoparia* acts directly on the key adipocyte differentiation factors. *Sphacelaria* inhibits pre-adipocytes from maturing into adipocytes and reduces the activity of enzymes involved in fat accumulation: they are GLUT 4, the glucose transporter; FAT, the fatty-acid transporters. The pre-adipocyte, a type of mesenchydermal cell, is not allowed to turn into adipocyte and possesses fibroblast-like activity. The algae stimulates collagen I and IV fiber synthesis in adipocytes as well as collagen I synthesis in fibroblasts. This process

results in the reduction in the thickness of adipose tissue and, as a consequence, one can achieve skin remodeling and firming.

Figure 11a: untreated adipocytes

Figure 11b: adipocytes treated with *Laminaria digitata* extract

c. Fountain of youth

Laminaria digitata, an alga contains sugars with specific biological activity. As the fibroblasts age, they change shape, become larger and produce less collagen. Older fibroblasts have markers of senescence such as beta galactosidase as well as chaperone molecules APJ. The application of *Laminaria* extract gives fibroblasts their "young appearance," the senescence factor disappears but the chaperone molecule remains. Collagen synthesis of mature skin then returns to the same condition as found in young skin. Skin is tightened and wrinkles are filled in.

Figure 13: anti-wrinkle effect of a Laminaria digitata extract, before (left) and after (right) 28 days of daily application.

Tested *in vivo*, wrinkles are reduced (Figure 13) and the volunteers appear younger in appearance. So the rejuvenation effect at the cell level translates into rejuvenation of people's skin as well.

d. Oligosaccharides

Polysaccharides of marine origin can be severed, on a molecular level, into smaller oligomers called oligosaccharides. There are polysaccharides found in the

membrane of *Laminaria* with a repetitive structure of mannuronic acid (M) and guluronic acid (G) (Figure 14).

Figure 14: structure of the oligosaccharide obtained by depolymerization of the polysaccharide from membrane of *Laminaria*.

The team of Professor Kawada [8] discovered that the oligosaccharide made repeating units of M and G act as acofactor for EGF (Epidermal Growth Factor) and these can stimulate keratinocyte growth. Testing the Laminaria Oligo Alginate *ex vivo*, using skin-biopsy methods, has further confirmed that Professor Kawada's hypothesis was correct (Figure 15). The recovery from wounds, using skin biopsy techniques as the model, is faster with the treatment of oligosaccharides.

Figure 15: Cut area is indicated by the black arrows. On the left: wound-healing process in a cut human epidermis; on the right: wound-healing process in a cut human epidermis treated with the oligoalginate.

The addition of zinc to this oligosaccharide gave additional benefits such as acne control as well as wound-healing activities (Figure 16).

Figure 16: Observation of acneic skin before (on the left) and after (on the right) 1 month of daily treatment with the oligoalginate zinc chelated.

4.2.5.3 EXAMPLE OF THE USE OF MICROALGAE IN COSMETICS

a. Exopolysaccharides

Exopolysaccharides, also known as EPS, are high-molecular-weight polymers mainly composed of polymeric sugars [9]. They are produced and secreted by microorganisms/microalgae directly in their environment to provide protection, nutrition, or adhesion to objects and rocks. Each microorganism produces its own specific exopolysaccharides with a unique sequence of sugars.

The marine exopolysaccharides (EPS) have no land-based equivalent and represent a new and original growing source of interesting functional ingredients for the cosmetic field. They can be used to improve aesthetics and provide a slippery feel like polyorganosiloxanes. These materials can be used to deliver immediate benefits and are used as line-filler polymers, mattifying agents, sebum absorbers, exfoliators, boosters of immunity, etc.

For example, EPS that mainly consist of galacturonic acid (Figure 17) is capable of absorbing sebum (Figure 18) and providing both immediate and long-term effects in skin mattifying (Figure 19).

Figure 17: structure of the mattifying EPS

Figure 18: demonstration of the affinity of the mattifying EPS with sebum. Left: before gentle shaking; Right: after

Figure 19: mattifying effect of the EPS on the forehead, 1 hour and 8 hours after a single application.

On the other hand, EPS composed of galactose, galacturonic acid, glucose, glucuronic acid, and mannose (Figure 20) can form a second skin at the surface of the epidermis. These are useful to fill in fine lines (Figure 21) and decrease the depth of wrinkles (Figure 22).

Figure 20: structure of the filling EPS

Figure 21: Observation of skin surface using electron microscope, before (left) and after (right) the application of the filling EPS

Figure 22: visualization of the wrinkle-filling effect of the EPS, 15 minutes and 3 hours after a single application

EPS composed of repeating units of galactose and N-acetyl-glucosamine (Figure 23), are known to stimulate keratinocyte differentiation (Figure 24) and improve the natural exfoliation of the *stratum corneum*.

b. Photolyase

UV radiation causes dimerization of adjacent pyrimidine bases in DNA. This action is classified as DNA damage and it can lead to the cell death. Photolyase (EC 4.1.99.3) is an enzyme (Figure 25) that is present in many species such as *Anacystis nidulans*, a blue-green algae. Photolyases are DNA repair enzymes that repair damage caused by exposure to ultraviolet light.

The repair is activated by visible light and known as photoreactivation.

Figure 25: photolyase

In order to preserve the enzyme's repair activity, the best way to use this ingredient is by encapsulation in liposomes, which protect the enzymes' capabilities

and deliver them effectively. The ability to reduce DNA damage on skin is shown in Figure 26.

Figure 26: picture at the top showing a lot of fluorescence due to the important quantity of dimers. The picture at the bottom is one hour after the application of 1% of the liposome containing the photolyase. There are 45% less dimers (10).

c. Thioreduxine/thioreduxine reductase

At the origin of life there was less ozone and a more aggressive effect of UV light on the DNA of blue algae.

Some of these algae invented the "instant repair" taking the energy of light and using their photolyase to do an instant photorepair; while others did not have such an enzyme. The stromatolites mentioned earlier are made by the blue algae *Phormidium* and have existed for at least a billion years. The way they survived

is with their glucoside-biopterin (Figure 27), a cofactor that activates the enzyme thioredoxin—a small redox protein acting as powerful antioxidant and preventing the formation of dimers under UV attack (Figure 28).

Figure 27: Biopterin

Figure 28: *Phormidium* extract activates thioredoxine and less dimers are created (less fluorescence).

There is great value for the cosmetic industry in the category of sunscreens by combining the extract of both blue algae in formulations to achieve the maximum protection of the DNA present and instant repair activity.

4.2.5.4 EXAMPLE OF THE USE OF COASTAL PLANT IN COSMETICS

a. Retinol-like

The Rock Samphire (Figure 6) *Crithmum maritimum* is the sole species of the genus *Crithmum*. It is an edible wild plant found on southern and western coasts of Britain and Ireland, on Mediterranean and western coasts of Europe including the Canary Islands, North Africa, and the Black Sea.

More recently Rock Samphire has been evaluated for its applications in skin care: the samphire oil extract offers the benefits of retinoids but without the unwanted irritation and photosensitivity. The other "retinoid like" activities seen include reduction of sebum secretion, reduction of lines and wrinkles due to premature aging.

This active extract can up-regulate CRABp 2 (c Retinoic Acid Binding protein) receptor like retinol and down-regulate the genes responsible for cell cohesion (Figure 28). As the bridges between the cells are weakened, exfoliation of the skin will increase and leave the skin smooth and uniform.

Figure 29. Effect of *Samphira* on adhesion protein expression

A treatment with *Samphira* modulates expression of differentiation genes compared to vehicle-treated epidermis: (1) increase of cellular retinoic acid-binding protein (CRABPs II); (2) decrease of cytokeratine CK1 and CK6.

Samphira decreases the expression of genes such as desmocollin 3 and 4, desmoplakins I, II, & III—which are part of the desmosome structure. The application of retinoid derivatives modifies the expression of these genes (Humphries et al. 1998). In this way, corneocytes peel off more easily because their inter-corneocyte adhesion is reduced, thus leading to the reduction in the size of the cornified layer.

b. The discovery of AQP 8

Salicornia (Figure 5) is a halophyte (salt-tolerant) plant that grows in salt marshes, on beaches, and among mangroves. These are occasionally sold in grocery stores or appear on restaurant menus as "sea beans," but their resistance to dryness has

led to research in its moisturizing properties. It was a real discovery by Codif International to find that the oil extract of Salicornia stimulates AQP8 (Aquaporine 8, aka ammoniaporine) and AQP3 expression (Figure 29). Salicornia helps to rehydrate skin from many different angles. These include, for example: increasing production of urea, filllagrin, natural moisturizing factor (NMF), and lipids. Until this major finding, AQP8 had not yet been discovered in the skin.

As a result of using Salicornia treatment, skin hydration is improved and transepidermal water and urea are reduced.

Figure 29: increase of aquaporines by the Salicornia oil

CONCLUSION

This chapter provides an overview (albeit, brief) of marine ingredients that are used to reduce wrinkles, pore size, sebum flow, and dryness. They can also be used for tanning or whitening (see chapter 3 A.16) as well as for slimming or plumping. While the early "simple algae extracts" had a "typical" odor, advances in the technology have expanded our awareness of the import of the depth of technology and usefulness of more sophisticated algae and their extracts. There are more and more products featuring exopolysaccharides, enzymes, oligosaccharides, etc. arising from marine origin. The trend is expected to continue, as these ingredients are natural, sustainable when farmed appropriately, and well accepted by the public.

ABSTRACT

Perhaps no single cosmetic problem receives as much bad publicity as the subject of cellulite. To a great measure, this negative publicity is due to the many so-called experts in the field of cellulite. Scientific journals are replete within accurate descriptions of this condition. Greater success in dealing with this issue is hampered by the lack of basic understanding of this disorderthat produces emotional discomfort for a high percentage of women regarding their perception of beauty.

One would think a disorder that affects females almost exclusively would provide a clue to its cause. We call it a disorder because it is not truly a disease and in the true sense of the word, it is a natural consequence of a physiological process.

This chapter describes a possible explanation for the etiology of cellulite as well as suggestions for ingredients that can be useful in topical cosmetic applications. As far as the commonly known name, "cellulite," this is sufficient for our purposes since the more technical name, "gynoid lipodystrophy," does not shed any light on understanding the disorder, from a cosmetic point of view.

There are several reviews on the theories and treatment of cellulite, and for a more in-depth discussion, we refer the reader to reference 1.[1] Keep in mind that much that has been written about cellulite in the past ten years is not based on accurate facts and we must dig a bit deeper to gain an understanding of what the phenomenon is, what causes it, and how to deal with it from a cosmetic point of view.

The term "adipose tissue" has taken on an entirely new meaning in the last ten years. We know now that this is not just a storage tissue, or a protective cushion. Rather, such tissue is actually a highly dynamic metabolic organ that has multiple

functions. In this chapter we limit our discussion to cellulite and the adipose tissue. The reader, however, is referred to an interesting article on subcutaneous adipose tissue (2).

4.2.6.1 A POSSIBLE ETIOLOGY FOR CELLULITE

First, we need to look at the anatomy of cellulite. True cellulite occurs only on the buttocks and thighs, to a distance about four inches above the knees. Obviously there will be some variations between individuals, but for the most part cellulite does not occur on the abdomen or the arms or the breasts. Why? The adipose tissue inthe buttocks and thighs is reserved for nutritional purposes in pregnancy during lean times. The adipose tissue in the upper thighs and buttocks contains twice as many alpha-2 receptors as it does beta receptors. The alpha-2 receptor inhibits lipolytic, or fat-burning, action so that this fatty tissue is not easily mobilized.[2] *This is why dieting and exercise are not very effective in the treatment of cellulite.*

The second important area we must look at is the anatomical structure of the fat. The fatty tissue of men and women is structured in a series of connective tissue bands known as trabeculae. These tough collagen bands keep the fat in a somewhat ordered array and essentially two layers. See Figure 1 and Figure 1a below.

There is a deep layer of fat that rests immediately upon the muscles. This in turn is separated by a superficial layer of fat immediately under the dermal layer of the skin,which is a thin fascia, and is called the superficial fascia.

Within the literature there are several errors that identify four to five layers of fat, along with a second major error that identifies male fatty distribution as being in a crisscross of compartment-like containers. This error has spread continuously throughout the cellulite literature, for it is quoted in just about every article one reads. No one to the author's knowledge has ever duplicated the findings of this prior work by Nuremberger and Muller![i] These investigators used two-dimensional histological preparations of skin. It is quite difficult to visualize a three- dimensional structure with this type of preparation. They also did not have the advantage of three-dimensional ultrasound studies.

Current studies employing 3-D ultrasound do not show evidence of crisscross collagen structure, or differences between male and female structure, other than the quantity and thickness of the collagen trabeculations (see Figure 2).The only distinguishing characteristicbetween male and female subcutaneous fat is the following:female fat is thicker, as measured from the bottom of the dermis to the muscle layer then in the male. The fat globules are generally larger than in the male adipose tissue. One can see this in Figure 1. Notice the size of the lobules and the thicknessof the fatty layers.

Figure 1. Human Anatomy of Thigh Skin: Male vs. Female

Figure 1a. Male vs. Female Adipose Tissue. Inverted Contrast.

In cellulite, the primary structural abnormality lies in the disruption of the described collagen connective tissue bands. The collagen is known as Type I collagen, a tough ubiquitous structural component. In cellulite these bands are dissolved, either completely or partially, resulting in a disorganized and chaotic adipose tissue layers. This can be seen again in Figure 1 but can be more readily demonstrated by a 3-D ultrasound as seen in Figure 2.

Figure 2. A 3-D Ultrasound of a 5-cm square section of cellulite thigh skin from a 28-year-old female. Taken with 7.5 mHz transducer.The black area represents the adipose tissue. Fat does not reflect ultrasound.

The immediate question arises:What could possibly cause such destruction in an otherwise well- organized tissue? The answer is very surprising. It took one author, P.T. Pugliese, M.D.,tenyears to appreciate the fact that cellulite is not a fat disorder; rather,it is a consequence of another innocuous physiological process, collagenase destruction of endometrium. Dr. Pugliese searched for a source of

collagenase in the body that would have the power to dissolve type I collagen and which appears almost immediately after puberty.[3] The menstrual cycle appeared to be the most likely candidate. To appreciate the role of the menstrual cycle and the associated hormones and enzymes in the genesis of cellulite we must review the physiology of the menstrual cycle.

4.2.6.2 THE MENSTRUAL CYCLE

Briefly, the menstrual cycle produces a succulent hospitable environment for a pregnancy. In the absence of pregnancy, endometrium of the uterus (inner lining) must be discarded and renewed on a monthly basis. The renewable environment is known as the endometrium, and it greatly enlarges during the early phase of the menstrual cycle under the influence of estrogen. The major structural components are a collagen type I matrix and an adequate supply of small blood vessels. This is shown in Figure 3. While the hormone relationship is fairly well understood, the role of the destructive enzymes and associated cytokines is less well understood. The following explanation represents our current understanding of the biological compounds involved in the menstrual cycle.

The Hypothalamic-Pituitary-Ovarian System

Figure 3

4.2.6.3 THE MATRIX METALLOPROTEINASES

In the absence of a pregnancy, estrogen and progesterone fall to very low levels. This initiates a process that removes the endometrium by a collagenolytic process called shedding. Specific enzymes known as matrix metalloproteinases cleave the collagen fibers and break them down into peptides and amino acid, which are recycled in the metabolic pool. These enzymes originate from fibroblasts and perhaps other cells of the endometrium stromal cells in particular. These special enzymes are called matrix metalloproteinases, or MMPs.

Regarding our present focus, we will only cover the basics of MMPs to allow the reader to appreciation of the real nature of cellulite. There are four major classes of MMPs along with natural biological inhibitors, known as TIMPs, or tissue inhibitors of matrix metalloproteinases. The four classes of MMPs are: the collagenases, the gelatinases, stromelysins, and membrane-type enzymes (MT-MMPs). All of these enzymes contain zinc metal at the active site, are synthetized in an inactive form known as a preproenzyme and secreted into the extracellular matrix (ECM). They are activated in the ECM; they recognize and cleave the ECM components, and are inhibited by both serum inhibitors and extracellular specific MMP inhibitors.

The **collagenases** are grouped as MMP-1, MMP-8, and MMP-13. These MMPs can cleave many types of collagen including Types I, II, III, V, and XI, which are fibrillar.[4] When these collagen types are cleaved they become more soluble and form gelatin (the origin of Jello).

The **gelatinases**, MMP-2 and MMP-9, can now take over and attack type IV collagen (the basement membrane of the epidermis), fibronectin, and laminin.

The **MT-MMPs** appear to have a key role in this regulation as well as in controlling other MMPs.

TIMPs are tissue inhibitors of MMPs. There are four types TIMP I, TIMP II, TIMP III, and TIMP IV. We shall not discuss these compounds in detail.

4.2.6.4 THE MENSTRUAL CYCLE, MMPS, AND OVULATION

Keep in mind as you read this section that menses occur each month, and the rise and fall of these enzymes is critical to both ovulation and menstruation. Cellulite is a spinoff process of these enzymes, as are many of the other connective tissue disorders.(It is possible that as these proteolytic processes occur they may produce small peptides with antigenic properties that eventually result in antibody product against tissue components).[5] Ovulation is a major process necessary for an eventual pregnancy. In Figure 4 the steps of the process are outlined. Menses occur about two weeks after ovulation.

Figure 4

1. LH initiates a biochemical pathway that stimulates the production of progesterone, cytokines, and prostaglandins.
2. These biochemical agents act on granulosa cells and thea cells to produce MMPs and TIMPs.
3. The MMPs destroy the follicle, permitting the egg (ovum) to be released.
4. The TIMPs may orchestrate the formation of the corpus luteum by controlling cellular proliferation and steroidogenesis.

4.2.6.5 THE MMPS AND THE MENSTRUAL CYCLE

Following the late secretory phase in the menstrual cycle, there is a fall in the plasma levels of estrogen and progesterone. This is apparentlya critical step in the cycle that triggers actual menstruation. Since the endometrium is a thick mass of collagen and blood vessels it needs to be shed in a matter of days to allow for the new growth of endometrium. Vigorous and swift lysis of the interstitial matrix by proteinases[6] is required. Whilewe do not know all of the hormonal intricacies, we do know that the ovarian steroids, estrogen and progesterone, initiate the stimulation of endometrial fibroblasts to secrete MMP-1. After initiation by sex hormones,MMP secretion is under control of interleukin IL-1alpha.[7]

4.2.6.6 THE KEY STEP RELATING MENSES TO THE GENESIS OF CELLULITE

MMP-1 is triggered to be formed in, and secreted by, the fibroblasts—not only in the uterus but also in other fibroblasts of the body. This statement is based on the fact that women get MMP-associated diseases such as temporomandibular joint disease[8] and anterior cruciate ligament disease.[9] In the thighs and legs the main target is the collagen bands, that is, the trabeculae that support and separate the fatty tissue into finite compartments. These bands are broken down, causing the free fatty tissue to move upwards and laterally to fill the available space. Where there are no bands, the fat will herniate through the dermis and produce a hill (no bands), and valleys will be produced where the bands are still attached. *This is the basis of the undulating appearance of cellulite.* Fat is stored not only as reserve food, but also to protect certain areas of the body, and in the case of the female it provides sexual attraction. What can be done? Alas, the current treatments are based on traditional and erroneous concepts, some which are actually harmful in that they exacerbate the condition. Here's the inside picture of cellulite:

1. Fatty tissue is no longer confined to anatomical compartments.
2. Fat is expanded in a nonphysiological manner,with new fat cells filling newly created spaces.
3. As new MMP insults exacerbate this damaged tissue, repair becomes impossible.

What can we do to correct this situation? Considering that estrogen and related cytokines are the initiating force, we need first of all to stop the repetitive damage. Next we must institute an effective repair system that will restore the collagen to its normal physiological structure. Finally we must restore the fat to its normal configuration, which in effect will eliminate the signs of cellulite. It must be borne in mind that cellulite is the result of a continuous physiological process and though it is treatable it is not curable. Since body fat is the second largest producer of estrogen even at menopause, there will be endogenous estrogen that will continue this destructive process.

4.2.6.7 TOPICAL THERAPY FOR REVERSING THE APPEARANCE OF CELLULITE

Anti-estrogens—the key component

It is surprising that are oriental women have a very low incidence of cellulite. Perhaps it is genetically based, but it may also be related to the soy products they consume in their diet. Soy contains a very potent phytoestrogen known as genistein. Due to its structure similarity to 17β-estradiol (estrogen), genistein,

a phytoestrogen, can compete with it and bind to estrogen receptors. However, genistein shows much higher affinity toward estrogen receptor β than toward estrogen receptor α.[10] Isoflavones such as genistein and daidzein are found in a number of plants including lupin, fava beans, soybeans, and kudzu.

Figure 5. Genistein

Genistein has estrogenic activity 100–1000 times less than estradiol and is known to be a cell proliferator. While it has exhibited anticancer properties it has also been shown to promote certain estrogen-sensitive cancers. It would appear however that since a rather large part of the Asian diet consists of sources of genistein, the incidence of estrogen-sensitive cancers does not seem to be beyond the normal worldwide incidence.

As a blocking agent 0.5–1% in a topical product should be adequate to inhibit estradiol.

a. Chysin—an aromatase inhibitor

Estrogens are made from testosterone precursors by an enzyme known as aromatase. Blocking the action of aromatase will decrease the amount of estrogen in the body and increase the amount of testosterone. It is used primarily by bodybuilders, but has also found use in treating dark circles under the eyes.

b. Chrysin is a naturally occurring flavone, a type of flavonoid. It is found in the passion flowers *Passiflora caerulea* and *Passiflora incarnata*. It is also found in chamomile, in the mushroom *Pleurotus ostreatus*, and in honeycomb. At high concentrations, chrysin is reported to be an aromatase inhibitor *in vitro*. However, studies performed *in vivo* show that orally administered chrysin does not have clinical activity as an aromatase inhibitor. However, chrysin is effective topically and appears to have many positive physiological effects on skin, from decreasing pigment to preventing cancer.[11,12,13]

Figure 6. Chrysin

Chrysinis not very water soluble, but is soluble in a number of organic materials including alcohol. For starting cosmetic formulations, the authors suggest a 1% concentration. So many other ingredients can affect the solubility and penetration that the final concentration in the formula will need to be optimized by an empirical process.

c. DIM, or Diindolymethane

Diindolymethane is gaining popularity as an anti-aging product. It is the active ingredient in cruciferous vegetables that accounts for much of their activity, including their being anti-estrogenic. A good starting concentration for this ingredient for an anti cellulite topical preparation is approximately 0.5%. Considering its action is different than that of the flavonoids, DIM could possibly enhance the action of the other anti-estrogens.

4.2.6.8 AGENTS THAT BLOCK MMPS

After inhibition of estrogen, the next most important ingredient in an anti cellulite product would be one that would inhibit the action of the MMPs on degradation of collagen. In our laboratory grapeseed extract and pine bark extract would inhibit collagenase type I up to 70 percent at a concentration of 1.4%. At this level we have obtained the maximum inhibition, as there is no difference observed over that level. At levels as low as 0.5% some inhibition has been obtained, but this does not occur at levels above 30%. It is suggested that several anti-collagenase ingredients be tried in the formula to maximize the effect. Examples of such ingredients include: EDTA, EGTA, cysteine, and histidine.

4.2.6.9 MOBILIZING ADIPOSE TISSUE

It is a characteristic of adipose tissue to fill available space, since a well-known biological principle is that nature abhors a vacuum. One of the perpetuating mechanisms in cellulite is the continual replacement of fat that has been mobilized or displaced upward. In order to have the trabeculae replaced in an orderly fashion it is advantageous to mobilize the existing fat while at the same time the body is restructuring the connective tissue foundation for the replacement of new adipose tissue. What follows are several suggestions for ingredients that can help to perform this task.

The most potent mobilizers are the natural catecholamines of the adrenaline series. Exercise of course not only helps to mobilize fat, but at the same time will produce an abundance of catecholamines. There are of course additional agents, such as forskolin from the plant *Coleus forskolii*, growth hormone, thyroid hormone, leptin, and testosterone.

4.2.6.10 BLOCKING PHOSPHODIESTERASE

Phosphodiesterase is an enzyme that destroyed camp, which is needed to phosphorylate lipase. Lipase of course is the enzyme responsible for the hydrolysis of triglycerides to free the fatty acids from the glycerol molecule. Glycerol is metabolized as a carbohydrate entity while free fatty acids are then shuttled into the mitochondria for oxidation through the Krebs cycle and electron transport system. It is well known that xanthines will block phosphodiesterase. The addition of theophylline or caffeine would help to mobilize fat by allowing an increased production of cAMP.

4.2.6.11 SHUTTLING FAT INTO MITOCHONDRIA

Mitochondria are the energy-producing organelles in the cell. They mobilize and metabolize in the cytoplasm of the adipocyte intofree fatty acids. Thereafter, the free fatty acids shuttle into the mitochondria and are reduced to carbon dioxide, water, and energy via the Krebs cycle and the electron transport system. Carnitine is used as a carrier to shuttle the free fatty acids into the mitochondria.Carnitine transports long-chain acyl groups from fatty acids into the mitochondrial matrix, where through β-oxidation they are metabolized to acetyl CoA before entering the citric acid cycle. Fatty acids must be activated before binding to the carnitine molecule to form acylcarnitine by being attached with a thioester bond to coenzyme A (CoA). The acyl group on CoA can now be transferred to carnitine and the resulting acylcarnitine transported into the mitochondrial matrix.[14]

Metabolism of Triglycerides

Figure 7

4.2.6.12 REBUILDING COLLAGEN

With the damage to the connective tissue stopped, and the fat being mobilized, we are in a position to begin to reconstruct collagen. A first suggestion is to have the subject wear a pair of mild-compression pantyhose. By mild compression, this means that pressure should not exceed ten to fifteen millimeters in the toe and should gradually decrease pressure at the knee and mid thigh, so that groin pressure will be near zero. Any restrictive underclothing such as bikini underwear will impede the venous return to the heart and result in increased pressure in the interstitial tissues. By compressing the veins, the diameter of the vessel is reduced, which decreases the pressure in the vein by increasing the velocity of the blood flow (Bernoulli's law). This results in the interstitial fluid moving into the veins and the lymphatic vessels, thereby reducing the interstitial pressure. The net result is greater metabolic activity in the fatty tissues. This increased pressure has a dramatic influence on the dynamics of fluid transfer. One only needs to observe the edema in a woman's lower legs and feet after standing at work all day to see this process in action. Just sitting at a desk will cause venous blood to pool in the lower legs, since the only adequate method of returning venous blood from the leg is by walking. Generally the pressure in the feet of a standing individual is 90 to120 millimeters of mercury. The addition of the pantyhose will decrease the diameter of the veins, thereby increasing the velocity of the blood flow and decreasing the interstitial pressure, by virtue of Bernoulli's law.

4.2.6.13 COLLAGEN STIMULATORS

Perhaps no single natural product is better able to stimulate fibroblasts to produce collagen than asiatic acid, derived from *Centella asiatica*.[15,16] Vitamin C, or ascorbic acid, is able to stimulate the production of collagen to threefold and is an important addition to anti cellulite preparations.[17] Vitamin C of course is critical to cross-linking of collagen. In the treatment of cellulite, the critical phase is to rebuild the collagen, in a normal pattern. To achieve this, it is necessary that the subject be ambulatory and have a regular exercise program that principally involves walking. Since adipose tissue in the cellulite area, that is, the buttocks and thighs, is not easily mobilized because of the presence of a large number of alpha to inhibitory receptors, it will take some time to mobilize the fat and rebuild the connective tissue. Studies for efficacy therefore should be a minimum of 90–180 days.

4.2.6.14 CLINICAL STUDIES

Most clinical studies use thigh diameter as an index of efficacy. However, the skin surface topography, and the shape and position of the buttock are a far better parameter to measure. Figure 8 shows photographs of the female posterior of a subjects. Subject A is a photograph of a post-surgery patient who had a "butt lift"

and additional plastic surgery to produce more rounded buttocks. Subject B is the classical "rectangular cellulite buttock."

Since the buttocks usually represent the largest pendulant mass in the body, this soft overlying tissue, composed of skin and fat, would be subject to gravitational forces that will tend to not only pull it down,but force it together in the center. This is unlike the gravitational pull on the breasts which, due to the curvature of the chest, are forced down and out.

Subject of plastic surgery showing circular-type buttocks. This is a rectangular buttock somewhat exaggerated in size.

Figure 8. Shapes of buttocks

Additional Ultrasound Figures

Enhanced photo accentuates the surface irregularities. This is a far better parameter to measure than circumference of the thighs. Note how the buttocks are flat. This is very characteristic of advanced cellulite.

A 3-D system is employed in this ultrasound photograph to measure the volume of the herniated glob of fat. Each segment views the fat globules from a different side. The lower-left corner of the illustration is actually a top view of the globular. The white and blue illustration on the right illustrates the 3-D composite picture of the globule with an actual measured volume, 0.92 ml.

This photograph represents a 3-D ultrasound depicting slices made at 90 degrees to each other at the top of the photo. The lower-left corner shows a view from the top of the section; the right lower side is a 3-D representation showing from what part of the specimen the slice was taken. This is represented by the blue section.

CONCLUSION

Cellulite is a serious cosmetic disorder resulting from a normal physiological process. At present there is no known cure, but there is a rational approach to dealing with this bane of women's beauty. The etiology of cellulite is hormonal. It is a consequence of estrogenic activity on fibroblasts, resulting in destruction of collagen tissues that support the storage of fat in the thighs and buttocks. By blocking the estrogen receptors on the fibroblast, the estradiol effect is attenuated so that less collagenase is produced. By mobilizing the displaced adipose tissue, the fibroblast within the structure of the connective tissue of the dermis is able to restructure the lipid compartments. Effective approaches to dealing with reducing cellulite centers on blocking estrogen and inhibiting collagenase as well as mobilizing displaced fat and restructuring the collagen compartments within the fatty tissue. Much more needs to be known about cellulite, but unless the hormonal genesis forms the basis of our understanding, current approaches may not be adequate.

INGREDIENTS III
ANTI-AGING

TOPICAL RETINOIDS

Author
Aanand N. Geria, MD

ABSTRACT:

Topical retinoids are derivatives of vitamin A used widely in the field of dermatology. They are indicated for treating a variety of conditions including acne, psoriasis, pigmentary disorders, and photo-aging. Retinoids are available over the counter in cosmeceutical products or by prescription. The most common side effect is irritation, including redness, scaling, and dryness.

4.3.1.1 INTRODUCTION

Retinoids are derived from vitamin A and may be synthetic or natural. They are commonly used in dermatology to treat a wide array of skin conditions. This class of medication can be administered orally or topically; however, the latter is more common and will thus be the focus of this chapter.

The first topical retinoid was developed over 40 years ago in the form of all-*trans* retinoic acid (ATRA), which is otherwise known as tretinoin. It was brought to the market in the 1970s as a treatment for acne under the trade name Retin-A. It was not until 1986 that the beneficial effects of tretinoin on photo-aging were first published.[1] This breakthrough research spurred the development of numerous prescription and over-the-counter products designed to treat wrinkles and other signs of aging.

4.3.1.2 PHARMACOLOGY

Vitamin A exists in three forms: an aldehyde (retinal), an alcohol (retinol), and a carboxylic acid (retinoic acid), which is the active form in the skin. All-trans retinol is the form of vitamin A delivered to the skin by way of the bloodstream after the metabolism of dietary retinyl esters. Within the cell, all-trans retinol is either oxidized to form retinoic acid or stored as retinyl esters, depending on whether retinoic acid is needed by the cell. This may explain why topical retinoic acid is more irritating than topical retinol; it can't be stored and thus may overwhelm cellular processes and lead to adverse effects.

Retinoic acid and synthetic retinoids bind to specific receptors in the nucleus. There are two groups of receptors: RARs and RXRs. Each type is further subdivided into three subtypes: alpha, beta, and gamma. RAR-gamma is the most important mediator of retinoid activity in the skin. The drug-receptor complex then functions by influencing the transcription of DNA. Structural differences between retinoids determine their binding affinity to transport proteins and nuclear receptors, which ultimately affect their physiologic actions.

4.3.1.3 INDICATIONS:

a. Acne

The pathogenesis of acne is thought to involve four key elements: plugged follicles, inflammation, *Proprionibacterium acnes*, and excess sebum. Retinoids decrease the retention of debris in hair follicles, thereby preventing the formation of the microcomedo, which is thought to be the initial lesion of acne. In addition, anti-inflammatory effects occur through the inhibition of toll-like receptor 2, which down-regulates inflammatory mediators such as NF-κB, IL-8, and IL-20. Topical retinoids, however, do not directly inhibit excess sebum or *P. acnes* counts.

Because topical retinoids are effective in treating both inflammatory and non-inflammatory acne, they are considered a cornerstone of any effective acne treatment regimen. FDA-approved retinoids for the treatment of acne include tretinoin, adapalene, and tazarotene.

b. Melasma and Post-Inflammatory Hyperpigmentation

Retinoids are a valuable adjunctive treatment for disorders of hyperpigmentation often used in conjunction with skin-bleaching agents like hydroquinone. Retinoids function by blocking transcription of tyrosinase, inducing desquamation, dispersing pigment granules, and enhancing epidermal cell turnover.

Combination therapies, most frequently consisting of hydroquinone, tretinoin, and a topical steroid are thought to be superior to monotherapy in the overall management of melasma. Tretinoin allows for the epidermal penetration of hydroquinone and the incorporation of a topical steroid helps to lessen the irritation of retinoids and hydroquinone.[2]

c. Photo-Aging

Topical retinoids have been shown to ameliorate the deleterious effects of chronic sun exposure on the skin. Indeed, topical retinoids have been proven to reduce epidermal thinning and dysplasia, increase new collagen formation in the dermis, increase new vessel formation, and exfoliate retained debris in the hair follicles.[1]

As such, tretinoin is FDA-approved to treat signs of aging such as fine facial wrinkles, mottled facial hyperpigmentation, and tactile facial roughness.

The main over-the-counter vitamin A derivative is retinol. Long considered to be the original cosmeceutical, it is commonly formulated with moisturizers and antioxidants to be used as a nightly cream or serum. The concentration of retinol is usually 1–2%, but benefits can be seen with as little as 0.1%.[3] In general, retinol is less irritating but also less effective than prescription retinoids. Some examples of popular retinol-containing cosmeceuticals and pharmaceutical retinoids are given in Table 1.

4.3.1.4 ADVERSE EFFECTS

The major side effect of topical retinoids is local irritation, which may include redness, scaling, dryness, itchiness, stinging, and burning. Consumers may also experience increased sensitivity to ultraviolet radiation; therefore a sunscreen is recommended when using topical retinoids. Poor tolerance to these adverse effects is a common reason for noncompliance or discontinuation of the product. While using topical retinoids, it is important to avoid using products that contain salicylic acid or alcohol to minimize irritation.

Table 1: Examples of OTC and pharmaceutical retinoid products

OTC Retinol Products	Pharmaceutical Retinoids
RoC Retinol Correxion Deep Wrinkle Night Cream	Tretinoin (Retin-A, Atralin, Renova, Refissa, Avita)
Neutrogena Rapid Wrinkle Repair	Adapalene (Differin)
Skinceuticals Retinol 1 Maximum Strength Refining Cream	Tazarotene (Tazorac)
SkinMedica Tri-Retinol Complex

PEPTIDES FOR ANTI-AGING SKIN CARE

Howard Epstein, Ph.D.
EMD Chemicals
One International Plaza, Philadelphia, PA 19113

ABSTRACT:

The first peptides for cosmetic use were developed in the early 1990s. Since that time, peptides have become an increasingly popular "cosmeceutical" ingredient in anti-aging products. These interesting and useful molecules are comprised of chains of at least two amino acids linked by a "peptide bond." The peptide bond is a chemical bond characterized by a sharing of electrons between atoms that are formed between two molecules when the carboxyl group of one molecule reacts with the amino group of the other molecule. This relationship constitutes the primary linkage of all protein structures. There is a specific association between the amino acid sequence in the peptide chain and its resulting bioactivity. Peptides are typically active at very low concentrations. The major challenge for the use of these molecules in the cosmetic and personal care area is to develop a peptide and formulate it into a vehicle that can be delivered to the target site in skin in order for the peptide to be effective.

4.3.2.1 PEPTIDES FOR ANTI-AGING SKIN CARE

Introduction

The term "cosmeceutical" was introduced over forty years ago by the famous dermatologist Albert Kligman, M.D. The word is ambiguous from a regulatory point of view since, in the United States, there is no such defined category for skin care products that is regulated by the Food and Drug Administration. However, recognizing the legal schism that exists between "drug" and "cosmetic," the industry jumped at a chance to have a word that described the many new, effective ingredients it was developing that fell into the schism. Interestingly, at one point, Dr. Kligman told an audience he was sorry he had proposed the term, but, nevertheless, the industry needed a term to describe such materials.

It is generally accepted that cosmeceutical ingredients are safe, will not harm the individual and may actually be beneficial in skin care products. The market for "high performance" skin care products remains strong as an aging population seeks products to help restore its youthful appearance. The ingredients formulated in cosmeceuticals are important, as they provide the basis for efficacy and other marketing claims for the formulation. Peptides provide product differentiation and enhanced-performance claims, including "naturally derived" and other holistic "well-being" concepts. Such claims align with the popular concept of healthy aging (1). They are of high interest for use in cosmeceutical products, as they function to modulate cell proliferation, cell migration, inflammation, melanogenesis, protein synthesis, and cellular regulation. These materials are generally not considered immunogenic and they break down into natural amino acids conferring a high degree of safety for use in cosmetic products.

4.3.2.2 WHAT IS A PEPTIDE?

As stated above, a peptide is a chemical entity consisting of at least two amino acids that are joined together by a peptide bond. Alternatively, the peptide bond is called an amide bond, and is formed when the carboxyl group of one amino acid

chemically links to the amino group of the next amino acid, releasing a molecule of water (Figure 1). Surprisingly, the International Union of Pure and Applied Chemists (IUPAC) provides no specific definition of a peptide. Short amino acid chains are considered peptides; long amino acid chains are termed proteins. Peptides consisting of two amino acids are termed a dipeptide, three amino acids are called a tripeptide, and so on. Peptides consisting of less than 20 amino acids are referred to as an oligopeptide. A polypeptide may consist of 50 to 100 amino acids. Amino acid chains above this range are usually considered proteins. Peptides may be found in a variety of configurations. For example, they occur as naturally occurring peptide sequences: peptides generated by the chemical or biochemical breakdown of proteins and peptides synthesized from naturally occurring or synthetically derived amino acids. In addition to length, the most important characteristic of a peptide is the amino acid sequence. The sequence order is crucial with respect to the biological properties of the peptide. These molecules perform a variety of biological functions; they may travel around the body until they interact with a target receptor either on the cell surface or within the nucleus of the cell. The interaction triggers additional activity resulting in a biological response.

Figure 1: Chemical structure of a peptide bond. The star indicates location of the peptide bond site.

4.3.2.3 SKIN STRUCTURE AND PEPTIDE CATEGORIES

As discussed in detail in other parts of this text, skin is composed of three differentiated layers. The epidermis, dermis and hypodermis. The epidermis and dermis are separated by a basement membrane rich in extracellular matrix (ECM) proteins. ECM proteins include collagens, laminin, fibronectin, elastins, and proteoglycans (2). The ECM anchors cells and organs together and also serves as a mediator of receptor-induced interactions between cells. The dermis provides a supporting

matrix including collagen and elastin. The largest class of fibrous ECM molecules consists of the collagens, which include 16 different types of collagen. Collagen in the dermal matrix is composed of type I (80–85%) and type III (8–11%) collagen. Collagens are primarily responsible for the tensile strength of skin (3). Damage to the collagen network causes healing to take place. Cellular behavior in the ECM is related to signaling by matrix components to cells through cell membrane receptors. Common receptors are known as integrins, and are found on the cell surface. Some of the signaling molecules are produced by proteolytic degradation in the ECM that release soluble peptides termed matrikines (4).

Signal Peptides-Matrikines

Matrikines result from the degradation of extracellular matrix proteins. They function as cell messengers involved in wound-healing and tissue repair. Matrikines are peptide fragments released by the process of enzymatic protein breakdown during tissue renewal (5). Two classes of matrikines have been characterized: natural matrikines that signal directly from the extracellular matrix area, and cryptic matrikines that require separation of peptide bonds for cell signaling (6). Matrikines are found in collagen, elastin, decorin, laminins, fibronectin, and tenascins. Palmitoyl pentapeptide-3 introduced by Sederma is an example of a matrikine peptide. The trade name for this peptide is Matrixyl®. According to the patent filed in 1999 and subsequent publications, 50 parts per million (ppm) of this peptide have been shown to produce a significant benefit to lines and wrinkles around the eyes when compared to the vehicle alone in a randomized study (7, 8). Thus, this technology falls into the characterization of peptides as interesting and useful skin anti-aging ingredients.

Antioxidant Peptides

Reactive oxygen species (ROS) can damage cells by oxidizing membrane phospholipids, proteins, and nucleic acids.

The damaging effects of ROS are normally kept under control by endogenous antioxidant systems including glutathione, ascorbic acid, and enzymes such as superoxide dismutase (SOD), glutathione peroxidase, and catalase. When these systems are excessively stressed by ROS, resulting oxidative reactions damage exposed cells (9). Large doses of antioxidants have been found to be effective in many animal models of diseases associated with oxidative stressors. Despite these observations, clinical trials with antioxidants in humans, such as vitamin E or recombinant human SOD, have generally failed to demonstrate significant benefits, leading to a proposed concept termed the “antioxidant paradox” (9). A possible

explanation for this paradox is that many of the antioxidants can also have pro-oxidant activity in addition to antioxidant activity. Such "bipolar" activity occurs especially in the presence of transitional metals such as copper (Cu (II). Another possibility for this paradox is that some of the antioxidants do not reach the relevant sites where free radicals are generated. Large proteins such as SOD do not penetrate cell membranes and are therefore ineffective against intracellular ROS.

Neuropeptides

There are functional and anatomical connections between the brain and skin. In the skin, "itch" (pruritus), excessive sweating (hyperhidrosis), and "flushing" (facial erythema), as well as many dermatoses such as atopic dermatitis, psoriasis, seborrhoeic eczema, prurigo nodularis, lichen planus, chronic urticaria, and alopecia areata, can be triggered or aggravated by stress (10). Neuropeptides released from cutaneous tissue and immune cells in response to stress stimuli are important for regulation of the cutaneous immune response and repair of skin. Since skin and brain are derived from the same type of tissue, this may help explain why peptides in skin act as neurotransmitters and other peptides are involved in itch, pain, pigmentary changes, and various forms of cutaneous inflammation (11).

Carrier Peptides

Carrier peptides function as facilitators of transport mainly for trace elements, including copper and manganese. In skin, this functionality is significant for wound-healing and regulation of various enzymatic processes. The tripeptide H-Gly-His-Lys-OH (GHK) was originally identified in human plasma and has a high affinity for copper^{2+} (Cu^{2+}). It acts as a signaling peptide and a carrier molecule for copper, which is a cofactor for several enzymes involved in collagen and elastin formation. The copper peptide was shown to stimulate wound-healing and to reduce fine lines and wrinkles (12, 13). By means of this mechanism, we again see the usefulness of peptides as "anti-aging" ingredients for skin.

Enzyme Inhibitor Peptides

Enzyme inhibitor peptides directly or indirectly inhibit enzymes. Several di- and tripeptides are known to be angiotensin-converting (ACE) inhibitors. ACE inhibitors are used to reduce blood pressure when taken orally. ACE inhibitors also prevent angiotensin I conversion to angiotensin II, a potent vasoconstrictor. Further, they also prevent the enzyme from inactivating the vasodilator bradykinin (7). Sederma has marketed a dipeptide, known as dipepetide-2, under the trade name Peptide VW commercialized for anti-aging skin care use (7).

4.3.2.4 BIOACTIVE PEPTIDES MARKETED FOR SKIN CARE PRODUCTS

A major challenge for cosmetic chemists working with peptides is to formulate the most appropriate peptide in a suitable vehicle to deliver the peptide to the appropriate target in skin at the appropriate time. This is a significant challenge in view of the fact that peptides are subject to: degradation by proteases in skin, undesired side effects that occur via interaction with different receptors in skin, and limited permeability into skin. To deal with these issues, chemically modified peptides are designed with enhanced bioavailability and stability, and this is a useful strategy employed by peptide manufacturers.

The most direct approach to achieving the goal of delivering the peptide intact is to modify side chains of single amino acids. The introduction of side-chain functional groups that do not occur naturally in peptides restricts their conformational flexibility and enhances metabolic stability. Another approach is to modify the peptide chain itself (14). A third approach is to construct the peptide with non-natural amino acids, which can enhance the stability of the peptide and provide further biological benefits (14).

Small peptides contain two to five amino acids, medium-sized peptides consist of four to 50 amino acids, and long peptides contain 40 to 80 amino acids. Small proteins contain 70 to 120 amino acids. The solubility of a peptide in an aqueous solution is largely dependent on the amino acid composition. Peptides with a large proportion of basic and acidic amino acids are likely to be readily soluble in aqueous buffers at physiological common pH of approximately 7.4.NT Peptides are modified as determined by their intended use. For example adding a fatty acid, a palmitoyl group to a water-soluble peptide can enable it to penetrate the lipophilic stratum corneum of skin. A large number of polar amino acids will improve solubility in aqueous systems as well (15).

Improved delivery of the peptide to skin can also be achieved by means of the use of fatty-acid derivatives to increase the lipophilic property of the peptide. An example of this approach is palmitoyl pentapeptide-3 (pal-KTTKS), commercialized under the trade name Matrixyl® by Sederma. Matrixyl is a five amino-acid chain consisting of lysine-threonine-threonine-lysine-serine. Palmitoyl is a fatty-acid derivative intended to increase penetration into skin. Matrixyl is claimed to have an anti-aging effect in that it has been observed to reduce fine lines and wrinkles. GHK copper-binding peptide, originally isolated from human plasma, was discovered during the 1970s (16). This peptide is useful for enhancing wound-healing via stimulation of components in the extracellular matrix (7). Table 1 lists examples of peptides marketed as cosmeceuticals in skin care products.

Table 1: Common examples of peptides used in cosmetic products, mechanism of activity, source, peptide type, and application in skin care (7, 16).

Peptide/Trade Name	**Source**	**Peptide Type/Mechanism of Action**	**Alternate Names**	**Cosmeceutical Application**
Palmitoyl Oligopeptide/Biopeptide-CL	collagen	Signal Peptide/Stimulates collagen and glycosaminoglycans synthesis	Pal-GHK	Anti-aging, anti-wrinkle, skin moisturization
Palmitoyl tripeptide/ Syn®-col	Thrombospondin I	Signal peptide/ collagen synthesis via TGF-ß		Improves stretch marks, anti wrinkle, skin moisturization, improve skin tone.
Acetyl hexapeptide-3/ Argireline®	SNAP-25	Neurotransmitter inhibitor/Botox-like via SNARE inhibition		Anti-wrinkle, skin moisturizer, improve skin tone and firmness
Peptide/Trade Name	Source	Peptide Type/Mechanism of Action	Alternate Names	Cosmeceutical Application
Palmitoylpentapeptide-3/Matryxl®	Synthetic, procollagen I fragment	Signal peptide/stimulates collagen I, III, IV, fibronectin, elastin, and glucosamoglycan production.	Pal-KTTKS, palmitoyl oligopeptide	Anti-aging, anti-wrinkle
Copper tripeptide complex/Lamin®	Synthetic, human serum	Signal and carrier peptide/Promotes large collagen aggregate degradation and more regular collagen synthesis, elastin, proteoglycans, glycosaminoglycans		Anti-inflammatory, anti-wrinkle, after skin resurfacing, skin moisturizer, hair growth stimulation
Dipeptide diaminobutyroyl benzylamide diacetate/Syn®-ake	Synthetic, Waglerin 1	Neurotransmitter inhibitor/Botox-like via acetylcholine receptor, mimics effect of Waglerin 1 found in the venom of the Temple Viper	Tripeptide-3	Anti-wrinkle. Botox-like effect

An example of a modified "biomimetic" peptide is a five amino-acid peptide with a cyclic structure marketed by Merck KGaA, Darmstadt, Germany under the trade name RonaCare® Cyclopeptide-5, INCI name Cyclotetrapeptide-24 Amino-cyclohexane Carboxylate. The peptide consists of five amino acids. Of these, four amino acids; L-arginine, glycine, L-aspartic acid, and D-phenylalanine are found in nature, while the fifth amino acid, aminocyclohexane carboxylic acid (ACHA), is synthetic (Figure 2 and 3). The peptide is claimed to improve the appearance of wrinkles and fine lines.

Figure 2: A cyclic peptide consisting of the amino acids arginine ®, glycine (G), aspartate (D), and aminocyclohexane carboxylic acid (ACHA). The amino acid sequence R G D is known in the literature as an amino acid sequence for stimulating wound healing.

Figure 3: Chemical structure of aminocyclohexane carboxylic acid.

Arginine is an essential amino acid associated with wound-healing. Various publications report that peptides consisiting of arginine, glycine, and aspartic acid (RGD) facilitate wound-healing by binding to specific receptors that signal for collagen renewal. Penylalanine helps to stabilize the protein from breakdown caused by proteases found in skin. The non-natural peptide AHAC helps to keep the peptide stable and provide a cyclic structure that optimizes selectivity for the targeted integrin receptor in skin (17).

CONCLUSION

There is a growing demand for anti-aging ingredients as the world's aging population increases. Various publications have reviewed peptides commonly used in cosmeceuticals (7, 8, 16). Peptides have great potential for use in anti-aging products, as they have a multitude of properties suitable to address common complaints associated with aging skin. A major challenge to formulating with peptides is the ability to enable peptides to penetrate skin. Permeability is associated with acid dissociation constant, molecular size, binding affinity, solubility, and partition coefficient (16). Other important factors are the compatibility and stability of the peptide in the formulation (7). From the perspective of cosmetic "ingredient-seekers" and formulators, the family of peptides, from the simplest to the more complex chemical modifications, is and will continue to be a useful foundation for the application of creativity in designing new and more efficacious anti-aging ingredients.

ABSTRACT

This chapter provides a short introduction to microRNA biology, summarizing and discussing existing evidence for the role of microRNAs in the skin, particularly in epidermal differentiation and renewal, pigmentation, skin protection and dermal senescence. Some noncoding DNA regions of human genome are transcribed into noncoding RNAs (ncRNAs). Among these ncRNAs, microRNAs represent a major component of RNA interference-mediated gene silencing. MicroRNAs bind to complementary sequences on target messenger RNA (mRNA) transcripts, generally resulting in translational repression or target degradation, leading to subsequent gene silencing. Cellular protein expression and a large number of biological processes are influenced by microRNA regulation of gene expression. Indeed, the critical phenotype of mice lacking key enzymes of the microRNA biogenesis pathway in the skin confirmed the essential function of microRNAs in their tissue. Moreover, a growing body of evidence supports the concept that microRNAs have an essential role in orchestrating the morphogenesis and homeostasis of epidermis and skin appendages. Profiling studies have identified numerous differentially regulated microRNAs associated with physiological and pathological processes. Among them, miR-203 is specifically expressed in keratinocytes and plays a crucial role in the epidermal differentiation processes.

4.3.3.1 RNA INTERFERENCE AND MICRORNAS—TIMELINE OF THE DISCOVERIES

The completion of the Human Genome Project in 2003 has confirmed that a large amount of DNA sequences (98% of the genome) are not protein-coding regions. Moreover, these noncoding regions are not simply "junk DNA" (Ohno 1972) but have a major regulatory role in gene expression. About 43% of noncoding DNA is transcribed mainly as introns and noncoding RNAs (ncRNAs). Among ncRNAs, short interfering RNAs (siRNAs), microRNAs (miRs), Piwi-interacting RNAs (piRNAs), small nucleolar RNAs (snoRNAs), and long ncRNAs (lncRNAs) are involved in RNA interference (RNAi). RNA interference (RNAi) is the inhibition of gene

expression by small double-stranded RNA molecules. MicroRNAs were discovered in the early 1990s in *C. elegans*. Since then, microRNAs led to extensive research, discoveries, exponential bibliographical publications, and studies with a growing number of microRNAs reported in dedicated databases such as MirBASE (www.mirbase.org) with 24521 entries (MirBASE v10, June 2013) and still counting.

a. Discovery of microRNAs

The discovery of microRNAs is very recent when placed in the timeline of the discoveries in genetics, covering these last two centuries (Figure 1, based on Darnell 2011). Briefly, the discoveries of the different amino acids extended from 1819 to 1935, and the study of the proteins started with the invention of the word "protein" by Jöns Jacob Berzelius in 1838 and culminated with the understanding of their structure and sequence (Frederick Sanger and Hans Tuppi 1951). Meanwhile, DNA was identified by Friedrich Miescher as "nuclein" in 1869, and the famous double-helical structure was elucidated by James Watson and Francis Crick in 1953, based in part on the work of Rosalind Elsie Franklin. RNA, although known for a long time, was first demonstrated to have a messenger role (François Jacob and Jacques Monod), then an adaptor role as transfer RNA, allowing gene expression. The central dogma of molecular biology, expressed by Francis Crick in 1958, explains the flow of information from DNA to protein; RNA being the intermediate. Finally, the uncovering of the genetic code explaining the correspondence between DNA coding sequence and the corresponding protein sequence is due to Marshall Nirenberg, in 1966. Only recently, however, has the regulatory role of noncoding RNA been evidenced, with the discovery of RNA interference and microRNAs.

Figure 1: Main discoveries in genetics.

b. The concept of RNA interference

Epigenetics was, until the end of the 1980s, a topic related only to chemical modifications of DNA or proteins, allowing transcriptional repression or activation. However, in the early 1990s, several studies reported *RNA-mediated inhibition of protein expression*, also called *gene-silencing*, occurring at the post-transcriptional level; which is related to epigenetics regulation of gene expression. First observed in plants by Richard Jorgensen and colleagues (Napoli et al. 1990), gene silencing was also described in the mold *Neurospora crassa* (Romano and Macino 1992), and named "quelling." These seminal observations introduced the concept of post-transcriptional gene silencing (PTGS) or RNA silencing (Figure 2).

Figure 2: Timeline of the discoveries in microRNA research.

In 1998, Fire and Mello observed in the worm *Caenorhabditis elegans* that double-stranded RNA (dsRNA) was capable of triggering sequence-specific inhibition of protein expression, a phenomenon that they called "RNA interference" (Fire et al. 1998). This term encompasses the post-transcriptional inhibition of gene expression by two types of small RNA molecules: *small interfering RNAs* (siRNAs) and microRNAs. Both siRNAs and microRNAs are small double-stranded RNAs. They differ in that siRNAs arise from long exogenous RNA precursors such as viruses, transposons ,or plasmids taken up by cells (they can also be applied on cells as synthetic siRNAs), while microRNAs are transcribed from the cellular genomic DNA and further processed.

MicroRNAs are small double-stranded noncoding RNAs (20–25 nucleotides in length). The first microRNA, Lin-4, was discovered in the worm *Caenorhabditis elegans* in 1993 by Victor Ambros and colleagues (Lee et al. 1993) and the first human one, *Lethal-7* or *Let-7*, was discovered in 2000 by Gary Ruvkun and

collaborators (Reinhart et al. 2012; Pasquinelli et al. 2000) (Ref Figure 2). The subsequent development of miR cloning alowed the identification of microRNA homologs in many vertebrate species, demonstrating the evolutionarily conservation of the major microRNAs across many species.

In only thirteen years, known human microRNA precursors reported in MirBASE, reached the number of 1872 (corresponding to 2578 mature microRNAs) (MirBASE v10, June 2013), giving evidence of the high interest of the scientific community for this new type of cellular components. The future elucidation of the entire human repertoire of microRNAs will be an important step in fully understanding their wide range of functions.

The discovery of RNA-mediated post-transcriptional regulatory mechanisms and the contribution to biology and medicine are so important that in 2006, the Nobel Prize in Physiology or Medicine was awarded to Andrew Z. Fire and Craig C. Mello for the discovery of RNA interference (Ref Figure 2), opening the way to breakthrough technologies to study the effects of the loss of function of specific genes in mammalian cells (Almeida et al. 2011) and to the use of these technologies in clinical therapeutics (Sindhu et al. 2012).

4.3.3.2 MICRORNAS – NOMENCLATURE, STRUCTURE, FUNCTION, MECHANISM OF ACTION

MiRNAs follow a particular nomenclature, allowing their identification in databases such as MirBASE, and insuring homogeneous principles of naming for the scientific community (Kozomara and Griffiths-Jones, 2014). The following are the main nomenclature rules for microRNAs. Hence, a sequential numerical identifier is assigned to each newly discovered microRNA: miR-29, miR-30, miR-31, etc. Usually, the mature microRNA sequences are designated “miR,” whereas the precursors and genes are labeled “mir.” The complete name of a microRNA should use a three- to four-letter code to indicate the species. *Homo sapiens* species, for example, will be indicated by the letters “hsa” (e.g., hsa-miR-29). In mouse, the prefix will be “mmu” (*Mus musculus*), whereas for drosophila, it will be “dme” (*Drosophila melanogaster*). In this review, as we will mainly refer to human microRNAs, unless stated differently, and we will use the microRNA name without indicating the letter code for species. Orthologous microRNAs in different species will bear the same numbering: for example, hsa-miR-29 in human and mmu-miR-29 in mouse. Lettered suffixes indicate related (paralogous) mature sequences, only differing at one or two positions—for example hsa-miR-29a and hsa-miR-29b, which are expressed from precursors hsa-mir-29a and hsa-mir-29b, respectively. Distinct genomic loci and precursor sequences that express identical mature sequences have numbered suffixes, e.g., hsa-mir-7-1, hsa-mir-7-2, and hsa-mir-7-3. Finally, the mature sequences are assigned names of the form miR-155

(the predominant product) and miR-155* (from the opposite arm of the precursor). A microRNA precursor can give two different mature sequences named -5p (from the 5' arm) and -3p (from the 3' arm).

MicroRNAs mediate their regulatory action through binding to the 3' untranslated region (3'UTR) of target gene mRNAs, usually resulting in translational repression and gene silencing (Bartel et al. 2004 and 2009; Feramisco et al. 2010). MicroRNAs are present in the entire genome, both as *intergenic microRNAs* and as *intronic microRNAs* (found in intronic regions of protein-coding transcripts).

RNA interference mediated by microRNAs, is a complex multi-step mechanism including transcription, nuclear processing, nuclear export, and cytoplasmic processing. MicroRNA biogenesis starts from the microRNA gene in the nucleus: intergenic microRNAs are transcribed by polymerase II (Cai et al. 2004; Lee et al. 2004) or polymerase III (Borchert et al. 2006) and give rise to a primary microRNA (pri-miR), whereas intronic microRNAs are co-expressed in the intron region of a protein-coding transcript, through a polymerase II-dependent promoter, and the resulting microRNA precursor (pre-miR) enters the microRNA pathway (Figure 3).

Figure 3: MicroRNAs: nuclear biogenesis, processing, and functions.

Pri-microRNAs are several kilobases long, capped, polyadenylated primary precursors, with hairpin-like structures, possibly polycistronic (i.e., bearing more than one microRNA). The stem-loop structure is cleaved by nuclear RNAse III Drosha, with the help of the double-stranded RNA-binding domain protein DGCR8, to release a microRNA precursor (pre-microRNA) (Cai et al. 2004; Lee et al. 2003; Lee et al. 2011). The Drosha-DGCR8 complex is called the "microprocessor" and allows nuclear maturation of primary microRNAs. All the previous steps occurring in the nucleus, the export of pre-microRNAs to the cytoplasm is mediated via the Exportin-5 protein (XPO5), and its cofactor Ran-GTP (Bohnsack et al. 2004; Lund et al. 2004). In addition to XPO5, Exportin-1 protein (also termed XPO1) can also participate in the export of microRNA precursors through the nuclear membrane, into the cytoplasm (Castanotto et al. 2009). Once in the cytoplasm, pre-microRNAs are further processed by the action of RNAse III DICER1 and TRBP cofactor, which remove the remaining hairpin structures to give birth to a microRNA duplex of 20 to 25 nucleotides in length. Finally, to be capable of modulating gene expression, one of the two strands of the microRNA, the mature microRNA, is loaded into the *RNA-Induced Silencing Complex* (RISC), which is composed of DICER1, TRBP, and the protein AGO2 (*Argonaute 2*) (Wilson and Doudna 2013). The integrated microRNA guides RISC to its specific mRNA targets either causing their degradation or directly inhibiting their translation into proteins (Feramisco et al. 2010).

Actually, depending on the degree of complementarity between the microRNA and the target mRNA, two different mechanisms of RISC-mediated gene regulation can occur (Doench et al. 2003; for review Stefani and Slack 2008). When the mature microRNA exhibits total complementarity with the target mRNA, the AGO2 component of RISC is capable of degrading mRNA, whereas if base pairing is incomplete, the silencing is achieved by preventing translation. Hence, microRNAs are capable of decreasing translation of human genes through two different silencing mechanisms. Moreover, each microRNA might target several messenger RNAs (Lim et al. 2005), and a single messenger RNA can also be targeted by multiple microRNAs (Brennecke et al. 2005). This increases the level of complexity in microRNA functions.

4.3.3.3 MICRORNAS REGULATE VARIOUS ASPECTS OF HUMAN PHYSIOLOGY AND EPIGENETICS

It has been estimated that human microRNA repertoire could reach or exceed 2000 genes, and that microRNAs may target 30% to 60% of the transcripts in humans (Friedman et al. 2009). Since microRNAs were recognized as a distinct class of biologic regulators with conserved functions, research has revealed their multiple roles in post-transcriptional regulation of gene expression, through transcript

degradation and translational suppression. Different sets of expressed microRNAs are found in different cell types and tissues (Lagos-Quintana et al. 2002). For example, among all microRNAs showing a cell-specific location/expression, miR-203 expression is restricted to keratinocytes (Sonkoly et al. 2007). By affecting gene regulation, microRNAs are likely to be involved in the main biological and physiological processes such as development and organogenesis (Stefani and Slack, 2008; Zhao et al. 2005), differentiation (Chen et al. 2004) proliferation and apoptosis (O'Donnell et al. 2005), growth control, stem cell activity, homeostasis, metabolism, signal transduction, and many others.

All the known mechanisms capable of altering the normal expression of a gene can affect the expression of a microRNA, including mutations and deletions, amplifications, chromosomal translocations, or transcriptional regulation dysfunction, leading to aberrant and dysregulated microRNA expression. Aberrant expression of microRNAs has been observed in numerous disease states, and microRNA-based therapies are under investigations (Tran et al. 2008; Li et al. 2009b; Fasanaro et al. 2010; Zhang et al. 2013).

4.3.3.4 MICRORNAS AND SKIN PHYSIOLOGY

a. Introduction on skin

The skin is the largest organ of the body, representing 15% of total body weight in the adult. Human skin shows a highly complex organization and involves the communication of multiple cell types. Skin is composed of three layers: the epidermis, anchored to a basement membrane (the dermo-epidermal junction), delimiting the underlying dermis and finally, subcutaneous hypodermis containing adipocytes. Skin is interspersed with various structures, such as hair follicles, sebaceous glands and sweat glands, blood vessels, lymphatics, and nerves.

Epidermis, the outermost layer of the skin, is a keratinized stratified squamous epithelium providing chemical, physical, and mechanical protection and serving as a first barrier to microbial infection. During the human embryonic development, epidermis is first constituted by a single-cell layer of ectodermal origin, the periderm, that will undergo a stratification process allowing the formation of the different layers of differentiated cells required to fulfill its barrier function (basal, spinous, and granular layers) (Figure 4). The main types of cells that make up the epidermis are keratinocytes, melanocytes, dendritic cells (including Langerhans cells), T-cells, and Merkel cells. The cells of the proliferative basal layer will alternatively differentiate into hair follicles.

Figure 4: Skin architecture and main processes regulated by microRNAs.

The mesenchymally derived dermis, mainly composed of matrix components (collagens, elastin, fibrillar proteins), also contains also cells, among which are fibroblasts, and immune cells such as mast cells, macrophages, dendritic cells, innate lymphoid cells, and T-cells (Heath and Carbone 2013). The integrity of the dermo-epidermal junction (DEJ) area, located between the epidermis and the dermis, is essential to ensure skin cohesion. Capillary blood and lymphatic vessels are spread throughout the dermis, and nerves access the dermis and the epidermis.

b. MicroRNAs and cutaneous biology

In the skin, microRNA-mediated gene regulation is involved in the main biological processes. To our knowledge, microRNAs were observed and described in skin for the first time in 2005 (Krützfeldt et al. 2005). The evidence of microRNA implication in skin has been demonstrated by the knockdown of DICER1 gene in mouse embryonic skin progenitors, which led to the epidermis-specific removal of microRNA activity and to a disturbed epidermal morphogenesis (Yi et al. 2006).

Many studies revealed that microRNAs are involved in skin homeostasis and cellular processes including development, stem-cell differentiation, signal transduction, metabolism, genomic stability, apoptosis, hair follicle development, skin and hair pigmentation, wound-healing and inflammation (Shilo et al. 2007;

Bostjancic and Glavac 2008; Sand et al. 2009; Feramisco et al. 2010; Hildebrand et al. 2010). MicroRNAs are also dysregulated in melanoma and nonmelanoma skin cancer (Kunz 2013; Sand et al. 2012)

Sets of microRNAs were identified as being important in skin physiology and function:

Holst and collaborators conducted a microRNA expression profiling study, in skin biopsies from eight healthy volunteers, and pointed out the 31 most abundantly expressed microRNA species in human skin (Holst et al. 2010). These microRNAs were selected because they had an expression level exceeding 100-fold over the background. MiR-574 appeared to be the most expressed, with almost a 450-fold expression compared to background. The microRNAs identified in this study are as follow (in increasing abundance): miR-203, miR-200c, miR-296-3p, miR-765, miR-539, miR-34a, miR-323-5p, miR-638, miR-608, miR-122, miR-145, miR-23b, miR-768-5p, miR-23a, miR-768-3p, miR-32, miR-206, miR-210, miR-205, miR-297, miR-672, miR-125b, miR-923, miR-574-5p, miR-595, miR-654-5p, let-7f, let-7d, let-7a, let-7c, and let-7b (Holst et al. 2010).

As a review, Aberdam and collaborators set-up a list of 34 microRNAs expressed in the epidermis: miR-15b, miR-16, miR-17, miR-18, miR-19b, miR-20, miR-21, miR-24, miR-27a, miR-27b, miR-30b, miR-34a, miR-92, miR-93, miR-99b, miR-106b, miR-125a, miR-125b, miR-127, miR-130a, miR-133b, miR-141, miR-191, miR-200a, miR-200b, miR-200c, miR-203, miR-205, miR-429, Let-7b, Let-7c, Let-7f, Let-7g, Let-7i (Aberdam et al. 2008).

Studies of the miRNAome in various pathologies such as psoriasis (Sonkoly et al. 2007, Aberdam et al. 2008, for review), systemic scleroderma (Li et al. 2010), atopic dermatitis (Aberdam et al. 2008, for review), keloids (Li et al. 2013) pointed out the deregulation of the expression of various microRNA sets.

All these studies showed the growing importance of microRNAs at different cell type levels in normal and abnormal skin physiology. The role of particular microRNAs of physiological relevance will be discussed in the following paragraphs.

c. Epidermal renewal and skin barrier

Skin integrity requires an efficient epidermis renewal to maintain the skin barrier function throughout life. The constant renewal of the epidermis is supported by progenitor cells mainly located in the basal cell layer, able to proliferate and to asymmetrically divide to engage suprabasal differentiation (Muffer et al. 2008; Pincelli and Marconi, 2010). These progenitors, also called *"keratinocyte stem cells"* (KSCs) or *"somatic stem cells of the epidermis"* (SSCEs) reside in a special microenvironment called *niche*, in the basal epidermis, and constitute less than 1% of the basal population. A delicate equilibrium between stemness and

differentiation controls epidermal renewal. Keratinocyte differentiation is a highly coordinated multi-step process regulated by autocrine and paracrine intercellular signaling mechanisms (such as growth factors . . .), and other external stimuli, leading to the expression/repression of genes and microRNAs. SSCEs are also observed in other compartments such as hair follicles and sebaceous glands, corresponding to cellular reservoirs (Beck and Blanpain 2012).

In the epidermis, several microRNAs regulate keratinocyte differentiation, but the most important player in this process is miR-203 (Yi et al. 2008).

d. MiR-203 is a master regulator of epidermal differentiation:

MiR-203 has been identified as one of the highly expressed microRNA in healthy human skin (Holst et al. 2010). Sonkoly and coworkers showed that miR-203 formed a gradient with low expression in the basal cell layer and high expression in the more differentiated suprabasal layers, and that it was expressed more than 100-fold higher in skin compared to other organs in human, and that miR-203 was specific to keratinocytes (Sonkoly et al. 2007). MiR-203 pattern of expression is in accordance with an implication in suprabasal keratinocyte differentiation (Sonkoly et al. 2010).

Interestingly, miR-203 was shown up-regulated in psoriasis, a pathology in which keratinocytes show abnormal states of proliferation and differentiation (Bostjancic et al. 2008), suggesting that the fine homeostasis of this microRNA is necessary to maintain a healthy skin. MiR-203 has also been recently identified as specifically overexpressed during the earliest process, leading to the specification of embryonic stem cells into keratinocytes (Nissan et al. 2011).

MiR-203 is involved in the transition of KSCs to “transit-amplifying” keratinocytes (Aberdam et al. 2008; Beck and Blanpain, 2012). In the adult epidermis, miR-203 is detectable only in the upper layers (Yi et al. 2008). In addition, it has been shown that miR-203 overexpression–induced keratinocyte differentiation and miR-203 inhibition with a specific anti-miR (anti-miR-203) resulted in decreased expression of involucrin (a protein involved in the cornified cell envelope, in the *stratum corneum*) after calcium treatment (Sonkoly et al. 2010). MiR-203 permits the switch between basal keratinocyte proliferation and suprabasal differentiation, by repressing stemness, through the post-transcriptional repression of target genes expressed in basal KSCs (Yi et al. 2008; Sonkoly et al. 2010).

e. P63, SOCS3, Zfp281, JUN, and ABL1 are the major mir-203 targets in the epidermis:

Several studies have identified miR-203 target genes in skin. The major target described in KSCs is the transcription factor DNp63, the principal p63 isoform, represents a master regulator of the stratification process and is responsible for

maintaining the proliferative potential of the epithelial stem cells. By controlling the expression of DNp63, miR-203 is involved in the transition of "KSCs" to transit-amplifying keratinocytes, behaving as the molecular switch for epithelial stratification (Lena et al. 2008; Aberdam et al. 2008).

SOCS3, a negative regulator of the JAK/signal transducer and activator of transcription (STAT) pathway is another potential target, but this is subject to controversy, as contradictory studies exist: while Lena and coworkers showed that despite bio-informatic alignment of miR-203 with SOCS3 3'UTR, the levels of SOCS3 mRNAs were not decreased with the increase of miR-203 levels, when keratinocytes were stimulated to differentiate *in vitro* (Lena et al. 2008), another study demonstrated the degradation of SOCS3 transcript in a luciferase reporter assay (Wei et al. 2010).

Evidences indicate that miR-203 can be considered as a tumor suppressor, targeting well-known proto-oncogenes such as c-jun (commonly deregulated in a wide range of cancers, including skin tumors), and c-abl (Abelson murine leukaemia viral oncogene homolog 1, or ABL1). Similarly to other miR-203 targets in the skin, c-jun is preferentially expressed in the basal proliferative layer of the epidermis. The suppression of miR-203 in basal cell carcinoma tumors was associated with a marked increase of c-jun expression (Sonkoly et al. 2012). MiR-203 was also shown to control the expression levels of ABL1, a classic oncogene involved in hematopoietic malignancies, where miR-203 is epigenetically silenced by hypermethylation (Bueno et al. 2008). An additional potential miR-203 target expressed in the basal-layer keratinocytes, is represented by the zinc-finger protein 281 (ZNF281) that may contribute to the basal-suprabasal cell transition (Yi et al. 2006; Aberdam et al. 2008).

Finally, some miR-203 minor target genes such as the *endothelin A receptor* (EDNRA), and the *protein phosphatase eyes absent homolog 4* (EYA4), have also been reported in the basal layer of the epidermis (Hildebrand et al. 2010).

f. Other microRNAs important in epidermal renewal

To analyze changes in microRNA expression during keratinocyte differentiation, the expression of 377 microRNAs has been evaluated after calcium-induced differentiation of primary human keratinocytes *in vitro*, and compared to microRNA expression patterns observed in epidermal stem cells, transient amplifying or terminally differentiated keratinocytes isolated from human skin (Hildebrand et al. 2010). In these experiments, 13 up-regulated and 1 down-regulated (miR-376a) microRNAs were observed after three days of calcium treatment. After seven days of cultivation in the presence of calcium, differential expression reached the numbers of 55 up-regulated and 8 down-regulated microRNAs. The comparison of these expression patterns with the ones obtained

with the transient amplifying or terminally differentiated keratinocytes from skin, allowed the identification of a set of microRNAs that may cooperate during skin differentiation (Hildebrand et al. 2010). Indeed, apart from miR-203, nine additional microRNAs were associated with human keratinocyte differentiation *in vitro* and *in vivo*: 8 microRNAs up-regulated during differentiation (miR-23b, miR-26a, miR-27b, miR-95, miR-200a, miR-210, miR-224 and miR-328) and one microRNA down-regulated (miR-376a).

A recent study highlighted the role of miR-574-3p and miR-720 in the regulation of p63 expression, *via* the protein iASSP (Beck and Blanpain 2012, for review). p63 and iASPP are both expressed in the basal epidermal keratinocytes, and iASPP is involved in the regulation of several members of the desmosomal proteins, tight junction and gap junction components, and b1 integrin. The expression of the protein iASSP, under the control of p63, represses miR-574-3p and miR-720, diminishing their impact on the degradation of p63 transcripts, thus forming a positive autoregulatory feedback loop.

MiR-24 is expressed in the suprabasal layers of human epidermis and induces differentiation *in vivo* by controlling actin adhesion dynamics and cytoskeletal modification during keratinocyte differentiation (Amelio et al. 2012).

Another study reported that miR-200 and miR-205, both highly expressed in normal skin, targeted ZEB1 and ZEB2, the transcriptional repressors of E-cadherin, playing an essential role in maintaining epithelial stability (Banerjee et al. 2013).

Finally, the miR-193b/355a cluster has been very recently shown to have anti-proliferative and anti-migratory properties in human keratinocytes, consistent with potential tumor suppressor functions in the epidermis (Gastaldi et al. 2013).

g. Skin pigmentation

Skin pigmentation plays a critical role in skin protection at the cellular/DNA level, particularly at the level of the basal keratinocytes allowing epidermal renewal. Melanocytes synthesize melanin in special organelles called melanosomes, which upon maturation are transferred to keratinocytes, and form a supranuclear melanin cap, thus protecting genomic DNA from harmful effects of solar UV irradiation. Several biological processes are implicated in the control of skin pigmentation: melanocyte signaling pathways involved in the transcriptional regulation of melanogenic enzymes, tyrosinase and related enzymes, melanosomal packaging and transfer, autophagic melanin scavenging in keratinocytes, and inflammation (Cichorek et al. 2013). Each of these processes is potentially regulated by post-transcriptional silencing by microRNAs; however, further research will be needed to elucidate the whole mechanism.

There is a great interest in the scientific and medical community to study microRNAs involved in the progression of melanoma, a most dangerous form of skin cancer affecting melanocytes. Kozubek and colleagues determined the microRNA transcriptomic signature distinguishing specimens of melanoma from normal human skin and set up a list of 40 microRNAs. Top-ten microRNAs deregulated in human melanoma was as follows: miR-205, miR-211, miR-15b, miR-26a, miR-451a, miR-203, miR-23b, miR-26b, miR-877, and let-7i-5p (Kozubek et al. 2013). One remarkable member of this list is miR-203 (down-regulated in melanoma), the well-known regulator of keratinocyte differentiation, that evidently also plays a role in melanocyte pigmentation. Hence, the decrease of miR-203 was described to play a pivotal role in melanoma, through reducing melanosome transport and promoting melanogenesis by targeting kif5b, the kinesin superfamily protein 5b, and through negative regulation of the CREB1/MITF/Rab27a pathway (Noguchi et al. 2013).

Albeit the majority of the studies on microRNAs and pigmentation report the modulation of microRNA expression in melanoma cells, several studies on normal human melanocytes NHEM pointed out the potential role of specific microRNAs in human skin pigmentation:

Wu and colleagues described in 2008 the effect of miR-434 targeting tyrosinase in human melanocytes (Wu et al. 2008). A study in Alpaca melanocytes showed the implication of miR-25 as a regulator of pigmentation, targeting MITF expression (Zhu et al. 2010). The increased expression of miR-145, by targeting genes implicated in melanogenesis (Sox9, Mitf, Tyr, Trp1) and genes important for melanosome transport (Myo5a, Rab27a, and Fscn1), induced depigmentation (Dynoodt et al. 2013). In the same study, several microRNAs were identified after forskolin and UV treatment of mouse melanocytes: some of them were up-regulated (miR-130b, miR-182, and miR-9) or down-regulated (miR-125b, miR-139-5p, miR-145, miR-155, miR-193, miR-206, miR-218, miR-221, miR-222, miR-28, miR-335, miR-365, and miR-455), suggesting their implication in the regulation of skin pigmentation (Dynoodt et al. 2013).

In a recent publication, miR-125b was identified as a potent regulator of melanogenesis, as its expression level was inversely related to pigment levels (Kim et al. 2014). Interestingly, the authors demonstrated a modulation of miR-125b expression by methylation of the *MIR125B-1* gene promoter.

Surprisingly, microRNAs originating from other cell types seem to control melanocyte pigmentation: indeed, Kim and colleagues recently demonstrated that miR-675 was secreted in exosomes by keratinocytes, and that it could regulate melanocyte pigmentation through a mechanism involving MITF (Kim et al. 2013). This observation enlarges our vision of the mechanisms of action of microRNAs, and brings to our attention the potential role of extracellular microRNA-containing

exosome as cell-cell mediators (Hu et al. 2012). Exosomes containing mRNAs and microRNAs are also important in pathological context, as their content is modified in cancers such as melanoma, and their characterization may lead to the identification of useful diagnostic biomarkers (Xiao et al. 2012).

h. Dermal physiology

Several studies have investigated microRNA expression in dermal fibroblasts and showed their involvement in the compositional remodeling of the dermis by the regulation of fibroblast senescence and extracellular matrix (ECM) protein synthesis.

Gu and Iyer evidenced the implication of 33 microRNAs in the reentry of fibroblasts into the cell cycle and proliferation, through the regulation of three signaling pathways: the PI3K pathway, the JAK/STAT pathway, and the MAP kinase pathway. Several microRNAs belonging to the let-7 family (let-7b c, d, e, f1, f2, g, i) as well as several other microRNAs (miR-15a, miR-15b, miR-21, miR-22, miR-23a, miR-23b, miR-31, miR-34a, miR-99a, miR-100, miR-107, miR-125a, miR-125b, miR-130a, miR-143, miR-145, miR-199, miR-214, miR-221, miR-222, miR-320, miR-368, miR-376a, miR-424) were hence identified (Gu and Iyer, 2006). Additional microRNAs have been identified for their role in replicative aging and senescence in fibroblasts: down-regulated miR-17, miR-19b, miR-20a and miR-106a (Hackl et al. 2010); down-regulated miR-21, miR-143, miR-145, miR-155, and up-regulated miR-10b, miR-23a, miR-26a, miR-34a, miR-146a, miR-199, miR-542 (Bonifacio and Jarstfer 2010); up-regulated miR-152 and miR-181a, targeting respectively integrin α5 and collagen XVI (Mancini et al. 2012); down-regulated miR-7, miR-18, miR-20, miR-29a, and up-regulated let-7b, miR-26, miR-30, miR-125a, miR-181, miR-199, implicated in fibroblasts proliferation and regulation of ECM synthesis (Suh et al. 2012); miR-29 and miR-30, targeting b-myb and the pRb pathway implicated in the control of cellular proliferation (Martinez et al. 2011; Martinez and DiMaio 2011). Finally, members of miR-29 family (miR-29a, b, and c) were found up-regulated during induced and replicative senescence in fibroblasts (Feliciano et al. 2011; Uglade et al. 2011), particularly miR-29b, which is a potent post-transcriptional repressor of collagen type I (Cheng et al. 2010).

Deregulation of physiological context in the dermis leads to conditions that helped identify microRNAs regulating fibroblast functions. Scleroderma, or systemic sclerosis, is a localized or systemic autoimmune disease affecting the skin, with excessive collagen deposition, fibrosis, and vascular alterations. However, little is known about the exact mechanism mediating the excessive collagen expression. Several microRNAs have been associated with this disorder. For example, the decrease of microRNA let-7a observed in patients contributes to the

excessive expression of type I collagen (Makino et al. 2013). Levels of miR-92a in dermal fibroblasts and in the sera of patients with systemic scleroderma was found increased. In fibroblast. The increase of this microRNA targeting MMP1, a major protease degrading collagens in the dermis, may participate to the accumulation of collagens observed in this disease (Sing et al. 2012). Similarly, dermal fibroblasts and the sera of patients showed a decreased miR-150 level in patients suffering from scleroderma. As a result, integrin b3 and collagen I expressions were increased (Honda et al. 2013). In another study, miR-7 down-regulation was also evidenced in patients with localized sleroderma (Etoh et al. 2013). Similarly, variations in the seric levels of miR-206 and miR-21 was correlated with scleroderma, and was proposed as a diagnostic association (Koba et al. 2013). A microarray chip analysis, comparing the miRNAome of fibroblasts from patients with systemic scleroderma to healthy individuals, identified six miRNAs: miR-206, miR-133a, miR-125b, miR-140-5p (up-regulated), and miR-23b and let-7g (down-regulated) (Li H. et al. 2013).

The study of another skin condition, keloids, allowed the identification of microRNA modulating the expression of collagens. Keloids are an overgrowth of scar tissue due to abnormal wound-healing process after skin injury, characterized by fibroblast proliferation and overproduction of extracellular matrix such as collagens. The study of microRNAs differentially expressed between keloid tissue and corresponding normal skin tissue pointed-out 32 microRNAs (Liu et al. 2012). Among them, up-regulated miR-21, miR-382, and miR-4269, and down-regulated miR-200c, miR-203, and miR-205 were validated by quantitative real-time PCR. A more recent study on normal and keloid skin fibroblasts revealed the differential expression of nine microRNAs, six of which were significantly up-regulated in keloid fibroblasts, including miR-152, miR-23b-3p, miR-31-5p, miR-320c, miR-30a-5p, and hsv1-miR-H7; and three were significantly down-regulated: miR-4328, miR-145-5p, and miR-143-3p (Li et al. 2013). MiR-196a was also shown to be involved in the expression of collagens during keloids formation (Kashiyama et al. 2012).

In conclusion, the dermis plays an important role in the aging process, resulting in altered appearance of the skin, and the emergence of wrinkles. The capacity of dermal fibroblasts to secrete good quality and sufficient quantity of extracellular matrix proteins through time is important to face the senescence process.

i. MicroRNAs and the hypodermal adipocytes

The process of adipogenesis corresponds to the differentiation of mesenchymal stem cells (MSC) into pre-adipocytes and then the maturation of these pre-adipocytes into functional adipocytes. Two principal types of fat are present in mammals: the white adipose tissue, which is predominant in adult human, and the

brown adipose tissue, present in significant amounts in newborns. Hypodermal adipocytes are part of the white adipose tissue and are involved in skin energy balance: they allow the storage of energy as fat in structures called lipid droplets. Lipid reserves occupy most of the cell space and can be released according to energy need in the tissue. Extracellular environment, hormones, and autocrine/paracrine signaling factors regulate adipocyte differentiation and maturation. The identification of microRNAs implicated in adipocyte metabolism is of high interest, in order to better understand hypodermal physiology and represent potential therapeutic targets against lipid storage disorders and obesity (McGregor and Choi 2011).

Several microRNAs have been identified as modulators of adipocyte physiology and obesity in mice. Indeed, the possibility to obtain genetically modified mice (expression knock-out of a given gene), specific mouse strains (such as *"ob/ob"* or obese mice), or adipocyte cell lines (such as 3T3-L1 pre-adipocyte cell line) designates these animals as a model of choice. A recent article reviews these microRNAs: Let-7, miR-15a, miR-17/92, miR-21, miR-24, miR-27, miR-31, miR-103, miR-107, miR-125b, miR-138, miR-143, miR-150, miR-200, miR-210, miR-221, miR-222, miR-326, miR-355, miR-378, miR-448, miR-519d (McGregor and Choi 2011).

Few studies are available on microRNAs involved in adipocytes growth and differentiation in humans. Essentially, the down-regulation of miR-155, miR-221 and miR-222 together seems to be required for adipocyte differentiation from human MSCs. These microRNAs act on two known key regulators of adipogenesis: the peroxisome proliferator-activated receptor gamma (PPARγ) and the CCAAT/enhancer binding protein beta (C/EBPβ) (Skårn et al. 2010). Another publication shows that miR-22 is able to influence negatively the differentiation of MSC in adipocytes: miR-22 expression inhibits MSC adipogenic differentiation and favors osteogenic differentiation by repressing the histone deacetylase 6 (HDAC6) (Huang et al. 2012). As for MiR-30, it was shown to induce the differentiation of MSC into adipocytes, by repressing osteogenic differentiation through targeting RUNX2 (Zaragosi et al. 2011). Another microRNA described in the inhibition of MSC differentiation in adipocytes is miR-138. Its overexpression revealed a reduced lipid droplet accumulation in cells, and a reduced expression of key adipogenic transcription factors such as C/EBPa and PPARg (Yang et al. 2011). MiR-21 seems to participate in adipocyte differentiation via the modulation of TGFb signaling (Kim et al. 2009). The inhibition of miR-26b is enough to reduce differentiation and formation of lipid droplets (Song et al. 2014). Another interesting microRNA is miR-27b, described to be able to suppress adipogenesis in multipotent adipose-derived stem cells by targeting PPARg (Karbiener et al. 2009). MiR-130 has also been reported to modulate PPARg and influence negatively adipogenesis (Lee et al. 2011). Recently, the knockdown of miR-143, a microRNA

already known to regulate adipocyte maturation by targeting mitogen-activated protein kinase 7 (ERK5) (Esau et al. 2004), did not reveal major changes, suggesting that miR-143 is only a fine tuner of the adipogenic differentiation and not a master regulator (He et al. 2013).

Specific microRNAs have also been identified in the brown adipose tissue. As an example, the miR-193b-365 cluster is a key regulator of brown fat development. These particular microRNAs are also involved in myogenesis repression for routing the differentiation to brown adipose tissue (Sun et al. 2011).

In conclusion, specific microRNAs can modulate and control adipogenesis (white or brown), and the deregulation of their expression may participate in fat accumulation disorders. Indeed, miR-519d has been associated with human obesity, implicated in regulating the expression of PPAR family members during adipogenesis (McGregor and Choi 2011).

j. Hair follicle morphogenesis

During the embryonic development, morphogenesis of hair follicles is initiated through interactions between the periderm cells and the underlying dermis, leading to localized invagination of epithelial cells to form hair follicles. The mature hair follicle is constituted of various layers of epithelial keratinocyte cells surrounding the hair shaft, and contains also specialized dermal fibroblast cells in the dermal papilla, and melanocytes, responsible for hair color. The outermost keratinocyte cell layer of the hair follicle, the outer root sheath, is contiguous with the basal layer of the epidermis. Hair follicles undergo cycles of growth (anagen phase), regression (catagen phase), and rest (telogen phase) (Alonso and Fuchs 2006). MicroRNAs play essential roles in hair follicle organogenesis, as the epidermal-specific Dicer deletion in mice resulted in hypoproliferative follicles, with no hair shaft (Andl et al. 2006).

Only a few studies report the role of microRNAs in human hair follicle morphogenesis and cycling, as most of them were performed on mice and other animals. However, a list of 31 microRNAs expressed in the hair follicle was compiled by Aberdam and collaborators: miR-15a, miR-15b, miR-16, miR-17, miR-18, miR-20, miR-21, miR-24, miR-27b, miR-92, miR-99b, miR-106b, miR-125b, miR-126, miR-127, miR-130a, miR-143, miR-152, miR-196, miR-199a, miR-199b, miR-206, miR-214, miR-351, Let-7a, Let-7b, Let-7c, Let-7d, Let-7f, Let-7g, Let-7i (Aberdam et al. 2008). The underlined microRNAs were also expressed in the epidermis. One microRNA of these lists, miR-196 (miR-196a-2) was recently shown to target tyrosinase expression, and a particular miR-196a-2 mutation (rs11614913 C allele) may account for a decreased risk of vitiligo (Huang et al. 2013).

Interestingly, miR-221, miR-125b, miR-106b, and miR-410 were found up-regulated in androgenetic alopecia (or male pattern baldness, MPB), suggesting their possible implication in the pathogenesis of MPB (Goodarzi et al. 2010).

4.3.3.5 INTEREST OF MICRORNAS IN THE EVALUATION *IN VITRO* OF ANTI-AGING DERMO-COSMETIC INGREDIENTS

a. Skin aging

Two distinct types of aging are affecting the skin, both contributing to structural and functional decline. Aging caused by our genetic inheritance and the changes in gene expression as time goes by, is called chronological or intrinsic aging, and can be mimicked *in vitro* by a high number of cell subcultures, known as "replicative senescence." The other type of aging is referred to as extrinsic aging, and is due to environmental factors such as sun exposure, and particularly repeated exposure to ultraviolet light (UV), overemphasizing the effects of intrinsic aging. It is noteworthy that environmental factors influencing skin aging are determining factors in the condition of mature skin, and play a central role in skin appearance impairment by inducing cellular senescence.

Whereas chronological aging is characterized by an atrophic pale skin (sun-protected) with fine wrinkles and laxity-inducing exaggerated facial expression lines, extrinsic aging leads to a rather hypertrophic skin, as the result of anti-inflammatory, anti-oxidant, and DNA-protectant responses to the damaging effects of UV irradiation. Moreover, photo-aged skin comes along with many manifestations ("age spots") corresponding to irregular pigmentation (e.g., freckles and solar lentigines); xerosis and leathery skin; senile purpura, cherry angiomas, and telangiectasias due to blood vessel abnormalities; comedones and premalignant skin tumors such as seborrhoeic keratoses; and a more pronounced wrinkling, compared to sun-protected aged skin.

b. MicroRNAs and cellular senescence

Cellular senescence is an "irreversible" state of cell cycle arrest that is induced during cellular aging and is involved in tissue maintenance (Bilsban et al. 2013). In the skin, senescence is associated with phenotypic changes in cutaneous structure and cells, and the appearance of markers of aging (senescence-associated beta-galactosidase, etc.). Many genes have been reported to be involved in the regulation of senescence: tumor suppressor genes (e.g., p53), senescence genes (e.g. p16, p21) and senescence suppressor genes (e.g., telomerase), oncogenes (e.g., MYC), stemness genes (e.g., SOX2), genes related with epigenetics (e.g., SIRT1, SATB1), inflammation-related genes, DNA damage signaling, cytoskeletal remodeling (e.g., TGF, WNT), and various transcription factors (Lafferty-Whyte et al.

2009; Olivieri et al. 2013). All these genes participate in a network of interactions regulating senescence, ending up with the highly regulated p53–p21 and p16–pRB pathways (Xu and Tahara 2013).

One strong piece of evidence that microRNAs can significantly modulate the senescence process *in vivo* is the conditional DICER ablation in adult mouse tissues, resulting in a premature senescence phenotype (Mudhasani et al. 2008). In regard to senescence regulation and induction, specific microRNAs have emerged as key modulators of the p53–p21 and p16–pRB pathways, and are related to inflammation, cellular senescence, and age-related diseases, cancer included. Hence, these microRNAs can be considered as *"inflammation-associated"* (inflamma-miRs), *"senescence-associated"* (SA-miRs), or *"cancer-associated"* (onco-miRs) (Bilsland et al. 2013).

Several publications reviewed the known SA-miRs (Lafferty-Whyte et al. 2009; Olivieri et al. 2013). Thus, Lafferty-Whyte and colleagues listed the main SA-miRs: miR-20a, miR-29c, miR-34a, miR-34b, miR-34c, miR-217, miR-369, miR-371, miR-372, miR-373, miR-499, let-7f (Lafferty-Whyte et al. 2009). Olivieri and colleagues recently updated this list, pointing out 27 human SA-miRs and 21 human inflamma-miRs, and observed 12 microRNAs common to the two lists. Interestingly, the majority of the microRNAs considered both as SA-miRs and inflamma-miRs (miR-9, miR-19a, miR-19b, miR-20a, miR-21, miR-29a, miR-126, miR-146a, miR-146b, miR-155, miR-181a, and let-7) are also deregulated in human cancers (Olivieri et al. 2013). Moreover, some of these microRNAs, and others, are associated with the most common age-related diseases (atherosclerosis, ischemic heart disease, diabetes mellitus type 2, kidney disease, cataracts, sarcopenia, osteoporosis . . .) (Schraml and Grillari 2012), confirming the importance of microRNA homeostasis in the aging process.

Interestingly, in very old people, a signature of up-regulated small noncoding RNAs (including microRNAs) was recently reported in circulating mononuclear cells from centenarians, compared to octogenarians and young people (Serna et al. 2012). The identified SA-miRs were miR-21, miR-130a, miR-494, miR-1975, and miR-1979. SCARNA17 (also called U91), a small nuclear RNA possibly involved in telomerase regulation, was also up-regulated in centenarians. The identification of this RNA signature may help us understand the molecular mechanisms and gene expression regulation endowing centenarians with extreme longevity (Serna et al. 2012).

Intrinsic senescence: The deregulation of particular microRNAs has been shown to play a role in intrinsic senescence. For example, SA-miR-22 was shown up-regulated in senescent fibroblasts, and suspected to be able to repress cancer progression by inducing cellular senescence, as it is known to be down-regulated in various cancer cell lines (Xu et al. 2011). In contrast, miR-24 was down-regulated

in senescent fibroblasts, whereas its target, p16 (pRB pathway), was up-regulated (Lal et al. 2008). MiR-34a is one of the microRNAs to have attracted a lot of attention, as it is considered a tumor suppressor regulating apoptosis in cancerous cells (Yamakuchi et al. 2008). MiR-34a up-regulation is observed in both permanent growth arrest states of replicative senescence, and in hydrogen peroxide–induced premature senescence of replicating lung fibroblasts (Maes et al. 2009). Interestingly, the epigenetics-related enzyme SIRT1, believed to regulate cell growth and apoptosis by deacetylating molecular targets that include p53, is a target of miR34a. Finally, miR-34a may also regulate the expression of transcription factor E2F3, which regulates cell-cycle progression (Yamakuchi et al. 2008). In epidermal keratinocytes, replicative senescence is associated with diffuse chromatin remodeling and epidermal terminal differentiation, and microRNAs are modulated during this process. As an example, miR-191 was identified as one of the most up-regulated miRNAs in senescent keratinocytes, targeting SATB1 (Special AT-rich Binding protein 1) and CDK6 (Cyclin Dependent Kinase 6) mRNAs (Lena et al. 2012). The identification of SATB1, a protein known as an epigenetic "higher order chromatin organizer" (Mir et al. 2012) implicated in the early development of epidermis (Fessing et al. 2011), suggests that up-regulation of miR-191 may lead to senescence-associated epigenetic modifications, inducing a new cellular gene expression profile, also inducing senescence (Lena et al. 2012). Another study reported that several SA-miRs (i.e., miR-138, miR-181a, miR-181b, and miR-130b) were up-regulated in human primary keratinocytes after replicative senescence, and participated in the regulation of ΔNp63 and SIRT1 (Rivetti di Val Cervo et al. 2012).

Extrinsic senescence: Other microRNAs were identified for their implication in extrinsic senescence. The deregulation of miR-15a, miR-20a, miR-20b, miR-93, and miR-101 has been shown to play a role in extrinsic senescence through targeting the p53–p21 and p16–pRB pathways (Greussing et al. 2013). A study pointed out the differential expression of miR-146a in UVA-irradiated fibroblasts, suggesting its implication in the regulation of aging-related genes (Li et al. 2013). MiR-34c, already known to be involved in intrinsic senescence, was also shown up-regulated in UV-induced senescence in cultured fibroblasts (Zhou et al. 2013).

The study of protein components involved in human diseases associated with phenotypic senescence led to the discovery of several microRNAs regulating their expression level. Nuclear lamins are a good example of such an approach. Lamin B1 (LMNB1) together with lamin A (LMNA) are major constituents of the nuclear envelope of cells. Lamin A mutations have been observed in a premature aging syndrome called *progeria*, whereas mutations in lamin B1 cause adult autosomal dominant leukodystrophy (ADLD). Decline of LMNB1 in senescent human dermal fibroblasts and keratinocytes was recently observed by Dreesen and

colleagues, showing that miR-23a could mediate the decrease of LMNB1 mRNA. This phenomenon is also observed in chronologically aged human skin tissue (Dreesen et al. 2013).

Cellular senescence has also been reported to be associated with the release of exosomes, which derive from lysosomes, a mechanism regulated by p53 protein in senescent cells. These senescence-associated exosomes can transfer microRNA and protein cargos between cells, mediating cell-cell communication during cellular senescence (Lehmann et al. 2008). Exosome-mediated microRNA transfer is an important mechanism of intercellular communication (Valadi et al. 2007) and potentially constitute a novel mechanism for long-range signaling during senescence. Hence, the release of exosomes from senescent cells may induce inflammation and microenvironment alteration in age-related diseases. Furthermore, the observation of intercellular signaling organelles open the door to investigate altered circulating microRNA levels as biomarkers of senescence (Lehmann et al. 2008; Bilsban et al. 2013; Xu and Tahara, 2013).

c. Tissue-engineering and microRNA studies

For the past few years, the use of bioengineered skin equivalents has encountered a strong development in pharmaceutical and dermo-cosmetical companies, allowing the access to reproducible and coherent testing models, as substitutes for cultured organotypic tissues and human skin. 3D reconstructed skin is a real technological advance allowing to obtain tissues close to *in vivo*, produced in a mastered environment with chemically defined medium, and has also medical applications in tissue-engineered skin bioconstructs for autografts, after severe burns or wounds (Shevchenko et al. 2010). Tissue reconstruction starts with primary cells extracted from human skin (keratinocytes, melanocytes, fibroblasts, etc.), obtained from patients undergoing surgery. Cells are then cultured in a specific medium and amplified in monolayer conditions to select mainly proliferative cells, that will be conserved frozen in liquid nitrogen, and will constitute a cell bank. The second step is the 3D reconstruction of a well-differentiated tissue, starting from the frozen cells. Epidermis can be reconstructed as a fully differentiated epithelium, with additional autologous cell types (e.g., melanocytes, to obtain a pigmented tissue) and also grown on a dermal-equivalent tissue, elaborated with autologous fibroblasts grown in a collagen scaffold (this model is sometimes referred to as "full thickness"), that will secrete proteins of the dermo-epidermal junction at the interface, with the aim to mimic the histological structure of normal skin, with both the epidermal and dermal layers.

Engineered epidermis and reconstructed skin constitute great models to study the role of microRNAs in skin, particularly keratinocyte proliferation and differentiation processes, or the relationships between keratinocytes and melanocytes

during melanogenesis and skin pigmentation. Models including a dermal equivalent compartment allow assessing the implication of microRNAs in fibroblast physiology, secretion of the dermal extracellular matrix, and communication between dermis and epidermis. Skin reconstruction also gives the opportunity to study microRNA expression in the context of the donor (influence of age, gender, ethnicity, skin phototype, epigenetic environmental factors . . .) and during the chronological differentiation of the skin epithelium. The use of anti-microRNAs or pre-microRNAs in these reconstructed models opens the way to study the effect of specific microRNAs on gene expression, protein localization, affected signaling pathways and biological processes, and the subsequent morphological and functional consequences.

CONCLUSION

Since the discovery of microRNAs in humans and the evidence of their expression in the skin, a growing number of researches proved that microRNAs are important regulators of the main biological processes, such as skin development, epidermal morphology, proliferation and differentiation of keratinocytes, hair morphogenesis, melanin production and skin or hair pigmentation, dermal ECM synthesis and adipocyte physiology. Microarray, RNA sequencing of microRNA, qPCR, and qPCR array are the main experimental approaches that have been developed to perform expression profiling of microRNAs, and to identify which are expressed in particular cell types, and their level of expression, under several conditions. It will be important in the future to better understand the mechanisms controlling microRNA expression, and the role of epigenetics, particularly DNA methylation, histone modifications, and chromatin organization. It will also be crucial to determine which microRNAs are important to ensure the physiological cohesion and the homeostasis of the skin, considered as a whole organ, and their role in other skin cell types such as Merkel cells, afferent neurons, immune cells, etc. Moreover, the deregulation of microRNA expression, either up- or down-regulated, observed in many skin pathologies and cutaneous cancers, shows that the impairment of microRNA expression may be implicated in the pathogenesis of these affections. In this case, microRNA signatures could serve as novel diagnostic markers of such pathological conditions. The role of extracellular, possibly circulating microRNA-containing exosomes has to be further investigated in an intercellular and inter-tissular context, and exosome content characterization may also serve for pathological profiling.

Elucidating the role of microRNAs and the processes they regulate in the skin, in healthy and in pathological conditions, will constitute important challenges for future research and therapeutic strategies.

GLOSSARY:

3'UTR: 3' untranslated region of a messenger RNA, located downstream of the stop codon.

AGO2: Argonaute 2 is encoded by AGO2 gene and is implicated in short interfering RNA mediated gene silencing.

BAT: Brown adipose tissue: Tissue specialized to burn lipids for heat generation and energy expenditure as a defense against cold and obesity.

B-MYB: *V-Myb Avian Myeloblastosis Viral Oncogene Homolog-Like 2.* B-myb is a member of the *myb* family of transcription factor, encoded by MYBL2 gene, and is a nuclear protein involved in cell cycle progression.

C/EBP β: CCAAT/enhancer binding protein beta, encoded by CEBPB gene. The protein can bind the promoter and upstream element and stimulate the expression of the collagen type I gene, and is also implicated in immune and inflammatory responses.

DICER1: A Ribonuclease III family enzyme. Dicer was given its name by Emily Bernstein, a graduate student at Cold Spring Harbor Laboratory, who first demonstrated the dsRNA "dicing" activity of this particular enzyme.

DGCR8: *DiGeorge syndrome critical region 8***.** This gene encodes a subunit of the microprocessor complex that mediates the biogenesis of microRNAs.

DROSHA: A Ribonuclease III family enzyme implicated in microRNA processing. The "microprocessor" is a complex comprising the RNase III enzyme Drosha and the double-stranded RNA-binding protein DGCR8, catalyzing the nuclear step of microRNA biogenesis.

ECM: Extracellular matrix. ECM is the extracellular scaffold present in all kinds of tissues, involved in tissue morphogenesis, differentiation, and homeostasis.

ERK5: *Extracellular signal-regulated kinase 5.* ERK5 is a member of the MAP (mitogen-activated protein) kinase family. Synonym: *Mitogen-Activated Protein Kinase 7* (MAPK7).

FSCN1: *Fascin Homolog 1, Actin-Bundling Protein.* This gene encodes a member of the fascin family of actin-binding proteins.

iASSP: *Apoptosis stimulating proteins of p53 (ASSP) inhibitor.* Also known as *Protein Phosphatase 1, Regulatory Subunit 13 Like* (PPP1R13B-Like).

miR: MicroRNA. A category of noncoding ribonucleic acids (RNAs).

MITF: *Microphthalmia-associated transcription factor.* The corresponding protein regulates the expression of melanogenesis enzyme genes.

mRNA: Messenger ribonucleic acid.

MYO5A: Myosin VA is an actin-based motor protein involved in cytoplasmic vesicle transport and mRNA translocation.

NHEM: Normal human epidermal melanocyte.

NHF: Normal human fibroblast.

NHK: Normal human keratinocyte.

Orthologous genes: Relates to genes for which the homology is the result of speciation. Orthologous genes are hence encountered in different species.

Paralogous genes: Relates to genes for which the homology is the result of gene duplication.

PKC: Protein-kinase C is a family of serine- and threonine-specific protein kinases involved in diverse cellular signaling pathways, that can be activated by calcium and diacylglycerol, and phosphorylate in a wide variety of protein targets.

PPARg: Peroxisome proliferator-activated receptor gamma nuclear receptors. PPARs form heterodimers with retinoid X receptors (RXRs), thus regulating the transcription of various genes.

pRb pathway: Retinoblastoma (Rb) pathway, involved in the control of cell proliferation and apoptosis.

RAB27A: Gene encoding a ras-related protein, belonging to the rab family of small GTPases.

RAN-GTP: *RAS-related nuclear protein*, binding a GTP molecule**.**

RISC: RNA-induced silencing complex, also known as *RISC loading complex* (RLC), or *microRNA loading complex* (miRLC). RISC is composed of DICER1, AGO2, and TRBP.

RNase III: Ribonuclease III enzyme. DROSHA and DICER1 are RNAse III enzymes.

RQ: relative quantification. RQ allows expressing of changes in gene expression, in a given condition, relative to a reference condition (e.g., untreated control).

RUNX2: Runt-related transcription factor 2. This gene encodes a member of the RUNX family of transcription factors, essential for osteoblastic differentiation and skeletal morphogenesis.

SCARNA17: Small Cajal Body-Specific RNA 17 (synonym: U91). SCARNA17 is a small nucleolar RNA (snoRNA) associated with small nucleolar ribonucleoproteins.

SIRT1: *Sirtuin 1 (Silent information regulator 1).* The encoded protein is a member of the sirtuin family, homologs to the yeast Sir2 protein.

SOCS3: *Suppressor of cytokine signaling 3.* This gene encodes a member of the *STAT-induced STAT inhibitor* (SSI), also known as *suppressor of cytokine signaling* (SOCS) family.

SOX2, SOX9: Transcription factors involved in embryonic development, stem-cell maintenance and in the determination of cell fate.

SSCE: Somatic stem cell of the epidermis.

TGFb: Transforming growth factor beta is a family of cytokines, including TGFb1 and 2, regulating proliferation, differentiation, adhesion, and migration in many cell types.

TRBP: *Transactivating response RNA binding protein*, also known as TARBP2, is a member of the RNA-induced silencing complex (RISC), with DICER1 and AGO2.

Tyr, Tyrp1, Tyrp2: Tyrosinase and Tyrosinase-Related Protein 1 and 2 are melanosomal enzymes involved in the melanin biosynthetic pathway.

UTR: Untranslated region.

WAT: White adipose tissue. Serves primarily to store extra energy as triglycerides, lipid droplets.

WNT: *Wingless-Type MMTV Integration Site Family.* Family of signaling proteins implicated in developmental processes.

XPO1: *Exportin 1*, or *chromosome region maintenance 1* (CRM1). The protein encoded by this gene mediates leucine-rich nuclear export signal (NES)-dependent protein transport.

XPO5: *Exportin 5.* This gene encodes a member of the karyopherin family that is required for the transport of small RNAs from the nucleus to the cytoplasm, in association with ran-GTP.

ZEB1, ZEB2: *Zinc finger E-box binding homeobox 1, 2.* The protein zeb1 is a transcription factor, whereas zeb2 is a DNA-binding transcriptional repressor.

AMINO ACIDS

ABSTRACT

Everyone ages.

Everyone wants to stop aging.

But is that really what we want? In this chapter, the author asserts that *we want to accumulate as many healthy years as possible but still maintain the appearance of youth and vigor.* Medical science has extended our life span and useful years dramatically by addressing disease and overall health issues. Cosmetic and Personal Care science can help mitigate the appearance of aging and increase one's overall attractiveness.

There are twenty "standard" proteinogenic amino acids that combine in unique ways to make peptides, proteins, enzymes, muscle, hair, skin, and organs. These twenty amino acids are also converted in the body through various metabolic pathways to produce useful substances. Amino acids topically applied exhibit useful properties such as acting as antioxidants, humectants, and free radical scavengers. They have also been shown to increase collagen production. Amino acids can also be derivatized "ex-somes" to produce cosmetically useful materials such as emollients, humectants, surfactants, moisturizers, and protectants that are beneficial in cosmetic formulation to address the appearance of aging. In this chapter we discuss the various amino acids, their derivatives, and the benefits to skin and hair formulation from a formulator's perspective.

It is our intention that this detailed chapter covering the structure and behavior of amino acids and their derivatives, on both skin and hair, will provide formulators and marketers with new pathways to create desired consumer products and to explore this interesting field further.

4.3.4.1 OVERVIEW OF AMINO ACIDS

a. Production

Amino acids are the building blocks of life. An amino acid is an organic compound that contains both an amino (NH-) functionality and a carboxylic acid (COOH) functionality. There are twenty standard amino acids that combine in specific ways to produce peptides, polypeptides, proteins, enzymes, muscles, and skin. These twenty amino acids are divided into nonessential amino acids and essential amino acids. The nonessential amino acids are those that we produce within our bodies in sufficient amounts for life and health. These are glycine, L-cysteine, L-alanine,

L-tyrosine, L-arginine, L-proline, L-aspartic acid, L-serine, L-glutamic acid, L-aspargine, and L-glutamine. The essential amino acids are just as important for life and health as the nonessential amino acids, but we do not make them or at least do not make sufficient amounts of them in our bodies to support life and health. Accordingly, we must obtain these amino acids from the food chain or more recently, from supplementation. The essential amino acids are L-mehtionine, L-tryptophan, L-threonine, L-phenylalanine, L-valine, L-lysine, L-leucine, L-histidine, L-isoleucine. Beyond these twenty biological important amino acids there are more than 500 other amino acids that are not useful biologically. There are also a myriad of derivatives that are designed for specific useful functions such as cleansing, moisturizing, lubrication, etc.

The Fermentation Method

"In 1908, Professor Kinue Ikeda discovered glutamic acid as a flavor component of seaweed and soy hydolysates. After neutralization with caustic soda, he isolated Monosodium Glutamate. This was not only the birth of the first industrial scale amino acid production from natural raw material hydrolysis but also the fundamental process for the isolation of other amino acids." [1]Most of the amino acids that are used in cosmetic and personal care products now are produced by a fermentation process using natural materials. In the fermentation method of amino acid production, microorganisms convert nutrients to various components necessary to themselves. Raw materials such as sugars and syrups are added to the microorganism culture and the proliferating microorganisms produce amino acids. Enzymes play a key role to degrade and synthesize substances. Consecutive reactions by 10 to 30 kinds of enzymes are involved in the fermentation process that produces the various high-purity amino acids.

It is necessary to screen the microorganisms to find the one that produces the greatest amount of the specific amino acid sought. Since one gram of natural soil contains on the order of 100 million microorganisms,[2] it is possible to pick out the useful one. There are a number of methods to select the microorganisms including mixing soil and water in a blender and then centrifuging the mixer. The microorganisms will be suspended in the supernatant.[3] They can then be cultured using the appropriate medium. In general, microorganisms produce the 20 amino acids in amounts necessary for themselves through a mechanism that regulates the quantities and qualities of the enzymes to yield amino acids in the amounts needed. "It is necessary to release this regulatory mechanism in order to manufacture the target amino acid in large amounts."[4]

The yield of an amino acid depends on the quantity and quality of the enzymes. Yield increases if the enzymes involved in the production of the target amino acid are present in large quantities, while it decreases if those enzymes are present in small amounts. "Suppose that a microorganism has a metabolic pathway

A->(a)->B->(b)->C->(c)->D (a, b, and c are enzymes). In order to produce only amino acid C in large amounts, one has to enhance the actions of only enzymes a and b and to get rid of the action of enzyme c. Strains are improved using various techniques to make this process possible."[5]

Other methods of producing amino acids are by enzymatic reaction and extraction:

- **In the enzymatic reaction method** an amino acid precursor is converted to the target amino acid using one or two enzymes. This allows the conversion to a specific amino acid without microbial growth eliminating the slower fermentation process from glucose.
- The **extraction method** entails natural proteins that are degraded to the various amino acids. The amount of each amino acid present in the raw material protein restricts the yield.

Overall, the fermentation method has the advantage of mass production at low cost.

From these twenty amino acids further derivitizations can be done to produce useful materials. The amino acids can be acylated and neutralized to form surfactants, acylated and esterified to produce emollients, cyclizated (via dehydration) to produce humectants, acylated to form functional products and neutralized to produce soap, etc. These and other derivitizations lead to many useful products for personal care applications, and more than about 500 "amino acids" recognized today.

b. Properties

There are twenty amino acids that are used by the body to produce proteins, etc. An amino acid is an organic compound that contains both a carboxylic acid group (COOH) and an amino group (NH2+) on the same molecule. An alpha amino acid is one in which the amino group is attached to the alpha carbon (that which is immediately adjacent to the carboxylate group). Further differentiation among the various amino acids is found in the side chains (R).

Fig. 1

This can be demonstrated in the following table:

Structures of Amino Acids (Table 1)

NONPOLAR, HYDROPHOBIC	R GROUPS	POLAR, UNCHARGED
Ajanine Aja A MW = 89		Glycine Gly G MW = 75
Valine Val V MW = 117		Serine Ser S MW = 105
Leucine Leu L MW = 131		Threonine Thr T MW = 119
Isoleucine Ile I MW = 131		Cysteine Cys C MW = 121
Phenylalanine Phe F MW = 131		Tyrosine Tyr Y MW = 181
Tryptophan Trp W MW = 204		Asparagine Asn N MW = 132
Methionine Met M MW = 149		Glutamine Gln Q MW = 146
Proline Pro P MW = 115		POLAR BASIC Lysine Lys K MW = 146
POLAR ACIDIC Aspartic acid Asp D MW = 133		Arginine Arg R MW = 174
Glutamine acid Glu E MW = 147		Histidine His H MW = 155

Solubility curves of amino acids that are relatively soluble in water

Figure 2

The solubility of L-Alpha Amino Acids is shown in the following charts:

The "breaks" in the curves of the behavior of some of the amino acids shown are the temperatures at which one mole of bound water is given up by that amino acid.

Solubility curves of amino acids that are relatively insoluble in water

Figure 3

It has been found that topically applied amino acids absorb into the epidermis and into the hair shaft. The first was done by a skin-stripping study and the latter through radio-tagged amino acids and amino acid analyzer.[8]

The amino acid analyzer measures the amino acids that are added to the hair shaft as well as those that are washed out. The radio tagging only measures amino acids that are added to the hair shaft. By using a combination of these analyses it is possible to determine how much amino acid penetrates the hair.

Figure 4

Figure 5

Function in Body Table 2: Amino acids as the building blocks of the body have many positive effects.

Valine Leucine Isoleucine	All of these three amino acids are called branched-chain amino acids (BCAAs). They perform the important functions of increasing proteins and serving as an energy source during exercise.
Alanine	It is an important amino acid as an energy source for the liver.
Arginine	It is an amino acid needed to maintain normal functions of blood vessels and other organs.
Glutamine	It is an amino acid needed to maintain normal functions of the gastrointestinal tract and muscles.
Lysine	It is a representative essential amino acid and tends to be insufficient when we are on a bread- or rice-centered diet.
Aspartic acid	It is contained in asparagus in large amounts. It is a fast-acting energy source.
Glutamate	It is contained in wheat and soybean in large amounts. It is a fast-acting energy source.
Proline	It is the main component of "collagen," which constitutes the skin and other tissues. It serves as a fast-acting energy source.
Cysteine	Cysteine can often be deficient in infants.
Threonine	It is an essential amino acid that is used to form active sites of enzymes.
Methionine	It is an essential amino acid that is used to produce various substances needed in the body.
Histidine	It is an essential amino acid that is used to produce histamine and others.
Phenylalanine	It is an essential amino acid that is used to produce various useful amines.
Tyrosine	It is used to produce various useful amines and is sometimes called aromatic amino acid together with phenylalanine and tryptophan.
Tryptophan	It is an essential amino acid that is used to produce various useful amines.
Asparagine	It is an amino acid that is located close to the TCA cycle (place of energy generation) together with aspartic acid.
Glycine	It is used to produce glutathione and porphyrin, a component of hemoglobin.
Serine	It is used to produce phospholipids and glyceric acid.

1.1 Derivatives of Amino Acids for Personal Care formulation:

Amino acids can be derivatized into many useful materials for formulation in the cosmetic and personal care field. The following chart shows just a few of the possibilities. Glutamic acid can be acylated with a fatty acid and neutralized to produce an anionic surfactant acyl glutamate. Glutamic acid can also be acylated and esterified to produce emollients, and it can be cyclized by dehydration to form a humectant. Aspartic acid can be polymerized and neutralized to produce polyaspartate, a film former and humectant. Latter sections in the chapter will discuss the use and benefits of many of these derivatives.

Fig. 6

The following are some of the reactions that are possible with amino acids:

Table 3

	Reaction of Carboxyl Group
1. Esterification* (peptide synthesis)	$\xrightarrow{R'OH}$ $H_2NCHRCOOR'$ Amino acid ester
2. Amidation (derivatization)	$\downarrow NH_3$ $H_2NCHRCONH_2$ Amino acid amide
3. Decarboxylation (derivatization)	$\xrightarrow[\text{or enzyme}]{\text{Heat}}$ H_2NCH_2R Amine
4. Reduction (derivatization)	$\xrightarrow{LiBH_4}$ $H_2NCHRCH_2OH$ Amino alcohol

Table 4

As formulators it is important to keep these possible reactions in mind.

	Reaction of α-Amino Acids
1. Chelation** (assay, identification, purification)	$\xrightarrow{Cu^{++}}$ Amino acid - copper complex
2. Hydantoin formation (derivatization)	$\xrightarrow{KCNO}$ Hydantoin
3. Azlactone formation (derivatization)	*N*-acetly amino acid $\xrightarrow{(CH_3CO)_2O}$ Azlactone
4. NCA formation (peptide and polyamino acid synthesis)	$\xrightarrow{COCl_2}$ *N*-carboxy amino acid anhydride
5. Diketopiperazine formation (derivatization)	$\xrightarrow{Heat}$ Diketopiperazine
6. Oxidation (assay, other applications)	$\xrightarrow{H_2O_2Fe^{3+}}$ $RCOOH+CO_2+NH_3$ $\xrightarrow{NaOCl}$ $RCHO+CO_2+NH_3$ $\xrightarrow{Enzyme}$ $RCOCOOH+NH_3+H_2O_2$ α-keto acid $\xrightarrow{Ninhydrin}$ $RCHO+NH_3+CO_2$

*Methylesterification, ethylesterification and benzylesterification are usually performed.
**Copper(II) glycine is used in threonine synthesis.

4.3.4.2 THE APPEARANCE OF AGING OF SKIN AND HAIR

We all see the signs of aging. Skin that is wrinkled, dry, and fragile. Hair that breaks easily, is dull and thinning. Sometimes these signs appear with the accumulation of years. Sometimes they appear as a result of disease, or of abuse, such as unprotected chronic tanning. Medical conditions must, of course be addressed by the appropriate physician. The personal care formulator can be and is equipped to formulate products that mitigate the appearance of aging and in some cases (e.g. the use of sunscreens) can prevent, the damage to a large extent before it occurs.

What are the antagonists of skin and hair?

Free radicals top the list. Free radicals are produced in all cells and in macrophages in large amounts. They support the immune system and are important for health. However, an excess of free radicals can attack healthy cells and tissue. Free radicals are highly reactive molecules that can damage cell membranes, lipids,

proteins, and DNA.[10] Species such as singlet oxygen, superoxide, lipid peroxides, hydrogen peroxide, and hydroxyl radicals can and do have significant effects on the skin and the hair. Formulations that counter the buildup of reactive oxygen species (ROS) go a long way towards mitigating the appearance of aging.

a. Skin

The skin is the largest organ of the body and is responsible for protecting it from environmental impacts. At the same time the skin sends a signal regarding the health and attractiveness of the person. Sagging skin, flaking dry skin, loss of elasticity, dullness—these are some of the signs of aged skin and are seen as unattractive.

The signs of aged skin can be caused by a number of things. These include, but are not limited to the accumulation of years, environmental damage, illness, poor diet, lack of exercise, and lack of sleep. Personal Care/Cosmetic Science can address these issues. Of course in the case of illness and disease the root cause must only be addressed by the proper medical professional, but even in this case personal care/cosmetic science can help the patient look and feel better while they are undergoing treatment and also afterwards. A good example of this is the American Cancer Society's "Look Good, Feel Better" program on how personal care/cosmetic science can help patients undergoing treatment.

There is significant evidence that topically applied amino acids penetrate into the epidermis. This was demonstrated by Maibach, et al.,[11] Coderch et al.,[12] Ruland et al.,[13] and others. But what effect do they have on the appearance of the skin?

The effect of absorbed amino acids into the skin results in a moisturiziation of the *stratum corneum*, thereby making the skin smoother and more supple.

It has also been shown that in the case of atopic dermatitis (dry, flaky, itchy skin), the amount of every standard amino acid normally present in the skin is significantly reduced, as is the total amount of these amino acids—which can be seen from the following graph.

Figure 7

The mechanism for this aspect of atopic dermatitis may be the decrease in amino acid metabolic conversion into metabolites in hyperkeratosis. Some of the metabolic pathways may be shown as in the following table.

Amino acid metabolism in stratum corneum (horny layer)

	Metabolic pathway
PCA	Glu → γ-Glu-AA → PCA (γ-Glutamyl-AA synthetase; γ-Glutamyl cyclotransferase)
UCA	His —NH3→ UCA (histidase)
Orn Cit	Arg —Urea→ Orn —carbamoyl phosphate, Pi→ Cit (arginase; ornitine carbamoyltransferase)
Ala	Asp —CO2→ Ala (aspartate 4-decarboxylase)

(S. Marstein, (1980): H. P. Baden & M. A. Pathak, (1967)
P. G. Crounse & S. Rothbera. (1961)

Figure 8

The rate of conversion to metabolites is greatly decreased in hyperkeratosis skin.

Rates of conversion to amino acid metabolites greatly decrease in induced hyperkeratosis. (SLS closed patch)

(J. Koyama, *J. Soc. Cosmet. Chem.*, **35**, 183 (1984))

Figure 9

The topical application of amino acids to the skin helps to mitigate the dryness, flaking, and itching of the skin and restores a more natural and healthy amino acid balance, again making the skin appear more youthful.

b. Wrinkling

Of all the things that adversely affect the skin and cause the appearance of aging under "normal" circumstances, free radicals and reactive oxygen species are arguably the worst offenders. Free radicals and reactive oxygen species (ROS) induced by environmental causes and UV radiation can overwhelm the skin's natural antioxidant defenses. This can lead to wrinkling, collagen breakdown, the loss of elasticity, and a myriad of diseases associated with oxidative stress.[14] It has been shown that topically applied antioxidants have a positive effect on the appearance and health of the skin.[15]

The work of Podda et al. was focused on vitamin C, vitamin E, ascorbic acid, tocopherol, and lipoic acid and showed that these small-sized antioxidants penetrated the skin with a positive effect. Amino acids are similarly small molecules and have indeed been shown to penetrate the skin. Cysteine (and cystine, since the S-S bond is easily broken), methionine, taurine, and N-acetyl cysteine are powerful antioxidants that will penetrate the skin. The tape-stripping work of Coderch et al. on threonine, isoleucine, and lysine shows that amino acids penetrate to 16 strippings, while Kawasaki, Sakamoto, and Maibach, working with glycine, sodium glutamate, proline, and threonine, show that there is penetration to 10 strippings.

Additionally, the prevention of ultraviolet light-induced wrinkles may be accomplished by the application of zinc pyrrolidone carboxylate prior to UV exposure.

Zinc PCA does this by interfering with the production of activator protein -1, AP-1. UV radiation initiates the formation of AP-1, which induces the production of collagenase. Collagenase causes the degradation of collagen, which then causes a wrinkle. If the cycle is broken, that wrinkle formation is stopped to a good extent. It has been shown in *in vitro* testing on human fibroblasts that 3 ppm zinc PCA inhibited 69.3% of AP-1 production and that 30 ppm of zinc PCA inhibited 77% of AP-1 production. It is expected that in *in vivo* work, somewhat more of zinc PCA would be required to produce the same effects.

Another cause of wrinkles is a lower rate of collagen production. If collagen production slows, the appearance of wrinkles increases. It has been shown that the topical application of an amino acid cocktail featuring a 1:1:1 molar ration of glycine: proline: alanine doubles the rate of collagen production. A 3:2:1 molar ratio of those same amino acids increases collagen production fourfold.[16] This goes a long way to reduce the appearance of wrinkles and is noticeable for as long as the application of the amino acid mixture is used.

Lysine has been reported to have a positive cosmetic effect on wrinkle formation. It is known that lysine is needed for the production of collagen and that lysine-poor diets may increase the development of wrinkles. The thought is that

since nutritional lysine supplementation has a positive effect on collagen production and it has been shown that topically applied amino acids also have a positive effect, then lysine topically applied may also help with the reduction of wrinkles. Other amino acids that have an effect on skin wrinkling are creatine, carnitine, arginine, and methionine. In these cases it has been reported that these amino acids stimulate regeneration of connective tissue.

Fine lines may be temporarily removed by the application of highly hygroscopic materials that supply moisture to the *stratum corneum*. Sodium PCA and proline are two candidates that have been shown to moisturize skin very efficiently. This moisturization "plumps" the skin slightly, removing the fine lines to a greater or lesser extent. Additionally, amino acid derivatives such as phytosterol/decyltretradecyl myristoyl methyl meta-alaninate binds in the order of 25 times its own weight in water, which provides a reservoir for the skin to use. Other analogs of this material such as phytosterol/behenyl/octyldodecyl lauroyl glutmate hold six times their own weight in water.

c. Elasticity

The topical application of amino acids and derivatives can increase the elasticity of the skin. Pig skin treated with sodium PCA has been tested using a Fudo rheometer. In this case, after treatment with a humectant, the rheometer measures the millimeters of skin elongation until it breaks.

<Method>
A sheet of pig skin (3mm*30mm) dipped in 10% each humectant solution for 1 hour was dried for 2 hours under 25°C / 40%RH. Then the elongation of each pit skin was measured until breaking.

<Result>

The effect of various humectant as softener for skin

Figure 10

Sodium PCA increases the elongation of the skin dramatically over that of untreated and just water-treated skin. It also shows better results than other common humectants. Similarly, amino acid cocktails comprised of sodium PCA, betaine, serine, glycine, glutamic acid, alanine, threonine, and proline have similar elongation effects.

A demonstration of the effects of sodium PCA treatment on the skin is as follows:

Sodium polyaspartate treatment increases elasticity a good deal. A 10% active ingredient treatment of sodium polyaspartate allows the skin to stretch 5.75 mm, while a 10% Active Ingredient treatment of hydrolyzed animal collage permits the skin the stretch 1.5 mm, and no treatment 1.25 mm. The measurements are done on a Fudo rheometer at 25°C and 40% RH. In this test a specimen is placed between two grips and the instrument stretches the specimen at constant rate until breaking. The length of the specimen at breaking is recorded and sometimes the breaking force is also recorded. This instrument is similar to a universal testing machine used in tensile strength measurements.

d. Clarity

<Method>
To induce the scaly skin. 1% SDS was applied to the forearm for 24 hours closed patch. After patch removal, each area was washed with the mild skin cleanser. 2 µl /cm2 of samples were applied to the test areas once a day for 3 days. Water holding capacity of the skin was measured quanitatively using skin surface hygrometer (Skicon 200, IBS INC.). Conductance values were measured at 25 °C. 40 RH%.

<Result>

Figure 11

The use of alpha hydroxy acids and beta hydroxyl acids has become almost commonplace to clarify the skin. In clarifying the skin the dead and dull skin cells at the surface are removed; a process that allows the healthy and "bright" skin cells to be seen. These materials are very good keratolitics that consume the dead surface skin cells, allowing the skin to look fresh and clear. A keratolitic is a substance that softens the skins keratin and allows the dead dull skin cells to fall off or be easily removed. One difficulty with alpha or beta hydroxyl acids is that these materials are very acidic and produce a stinging sensation. Their stinging can be reduced by adjusting the pH, typically form 3 to a pH of 4.5. However, the use of normal neutralizing agents such as NaOH of fatty amines to bring the pH to 4.5 will also reduce the clarifying effect of the alpha and beta hydroxy acids. The amino acid arginine, an alkaline amino acid, has been shown to have the ability to raise the pH of the alpha or beta hydroxy acid product without reducing its efficacy.[17, 18]

e. Hydration:

Hydration of the skin is a key to a youthful appearance.

It has been shown that there is a linear correlation between the amount of amino acids present in the *stratum corneum* (SC) and the degree to which the skin is hydrated. The greater the amount of amino acids present, the greater the hydration.

(Y. Kumano, *Fragrance Journal.*, **79**. 64 (1986))

Figure 12

Since fully hydrated skin is soft and supple, the increase in hydration due to the presence of amino acids makes the skin softer and more pliable as is youthful skin.

The skin's *stratum corneum* contains within the corneocytes the natural moisturizing factor (NMF) that helps the skin retain moisture and suppleness. This NMF is comprised of 40% amino acids, pyrrolidone carboxylic acid 12%, lactates 12%, urea 7%, ammonia, uric acid, glucosamine, creatinine, citrates, various salts, glucose, organic acids, peptides, and others totaling about 28% according to Spier and Pascher.[19]

The composition of the amino acids in the NMF is illustrated in the following graph.

Figure 13

As mentioned above, there is a direct correlation between the amounts of amino acids present in the SC and the degree of skin hydration. The more amino acids present, the greater the hydration and the greater the suppleness of the skin.

Derivatives of amino acids can facilitate hydration or the mitigation of damage to the NMF. It has been shown that washing with a simple cleanser containing 10% active ingredient sodium lauryl ether sulfate will remove about 62% of the amino acids in the SC and ~56% of PCA present in the SC relative to the initial amounts present. Soap will remove about 70% amino acids and 62% PCA again relative to the initial amounts present. A wash with 10% active substance of sodium lauroyl glutamate, a glutamic acid derivative, washes out only 52% amino acids and 39%

PCA of those initially present. This shows that the retention of amino acids and PCA can be influenced by the character of the surfactant employed to cleanse the skin. Similarly, the application of an amino acid–derived emollient can reduce the trans-epidermal water loss, thereby increasing hydration of the skin as reported by Ishii.[20]

Figure 14

Where cholesteryl/behenyl/octyldodecyl lauroyl glutamate (golden line), and Type 3 ceramide (red line), petrolatum (black line), and untreated (blue line). The phytosterol analogs of the glutamic acid–based compounds show similar results. The timeframe is Initial, the Zero hour post-damage, then one, two, and three days after application of the treatment.

L-proline is unique among the amino acids in its ability the increase moisturization, especially in the presence of leucine and isoleucine.

Figure 15

The graph above, Figure 15, contrasts the absorption of humectants at high-humidity and low-humidity conditions over the course of time. The humectants were initially dried to constant weight and then exposed to high, 65% RH over 15 days with the water weight uptake measured. At the end of day 15 the humectants were exposed to low, 35% RH for an additional 15 days with the water weight loss measured. The first case measures the greatest hydration from atmospheric moisture that can be expected to be attained while the second case measures the moisture retention under dry conditions.[21]

It can be easily seen that sodium PCA and sodium lactate absorb the greatest amount of moisture under high-humidity conditions but that L-proline retains the greatest amount of moisture relative to its initial hydration at low humidity. The low-humidity retention of moisture is important, since this is the condition that dries out the skin and causes it to be itchy and cracking.

Leucine and isoleucine establish a lipid bi-layer with water bound to L-proline. This bi-layer inhibits moisture loss from the skin.[22]

Figure 16

f. UV Damage

Amino acids and their derivatives are useful in mitigating the effects of UV radiation on the skin. It is important to note that these materials are not replacements for good sunscreens/sun blocks but augment their effects and protection.

Zinc PCA has been shown to prevent the formation of activator protein-1, which is caused by incident UV radiation. This inhibition prevents to a good extent the formation of collagenase and damage to collagen and elastin in the skin. Other amino acids such as cysteine, methionine, taurine, glutathione, and n-acetyl cysteine are powerful antioxidants and free-radical scavengers. When topically applied they augment the skin's natural defenses against reactive oxygen species induced by UV radiation and other environmental factors.

Amino acid derivatives like the ester isopropyl lauroyl sarcosinate are outstanding solvents for organic UBV absorbers and allow easy incorporation of these materials into a formulation and help inorganic UV blocks spread uniformly across the skin substrate. Lauroyl lysine is another derivative that helps inorganic UV blocks deposit uniformly on the skin. It also has the advantage of delivering a soft lubricious skin feel.

Materials such as phytosterol/octyldodecyl lauroyl glutamate and phytosterol/behenyl/octyldoddecyl lauroyl glutamate are excellent wetting agents for pigments used as UV blocks, such as micronized titanium dioxide and zinc oxide. These also allow a more uniform deposition across the skin.

4.3.4.3 HAIR

The function of amino acids in the hair is much less well understood than it is in the skin. Of course amino acids are constituents of keratin and an integral component of the cell membrane complex (CMC), which "glues" the cells of the cortex of the hair together.

We all start with healthy hair but with the modern propensity for washing, perming, and coloring, we damage it thereby causing breakage, dullness, loss of elasticity, and roughness. This damage shows up as lower tensile strength, cuticle damage, and components such as collagen, cholesterol, amino acids, fatty acids, and ceramides leaching out of the hair shaft. What are needed are materials that help repair the hair and/or mitigate the degree of damage in the first place. Amino acid derivatives can have a positive effect on the hair.

a. Breakage

The reduction in tensile strength from perming and bleaching results in severe hair breakage. It has been shown that the tensile strength of permed hair is only 95% that of normal healthy hair and the tensile strength of bleached hair is only 90% of

that of normal healthy hair. This reduction in tensile strength may seem inconsequential, but damage and breakage indeed occur.

Fig.17

In various tests it has been found that the addition of amino acid derivatives such as phytosterol/octyldodeyl lauroyl glutamate mitigates the damage done to hair from bleaching followed by shampooing. The testing procedure employed was to first take tensile strength readings on untreated hair in order to establish a baseline. Thereafter, hair was bleached with ammoniated peroxide in one case, bleached and shampooed with a 10% active sodium lauryl ether sulfate shampoo was employed in the second case, and in the third case the hair was bleached, and shampooed with a shampoo containing 0.5% phytosterol/octyldodecyl lauroyl glutamate. The untreated hair was normalized to 100% for comparison. The findings of these tests showed that bleached hair lost 5% of its tensile strength in the bleaching process, and that bleached and shampooed hair lost approximately 13% of its tensile strength. However, when 0.5 % of the amino acid derivative phytosteroyl/octyldodecyl lauroyl glutamate was added to the shampoo, the tensile strength of the hair returned to that of bleached only hair (95% of normal).

Similar effects were noted in permed hair that was first permed using an ammonium thioglycolate solution and then neutralized with a sodium bromide solution. Tensile strength measurements were made on permed hair in one case, on permed and sodium laureth sulfate–shampooed hair in a second case and on permed hair shampooed with phytosterol/octyldodecyl lauroyl glutamate added to the shampoo at 0.5% active. The results showed that permed hair retained only 75% of the tensile strength of normal hair and that shampooing further increased the damage so

that the hair retained only 65% of its tensile strength. By contrast, the addition of the amino acid derivative prevented further damage from shampooing, allowing the hair to retain about 78% of its normal tensile strength.[23]

In additional tests hair was bleached with ammoniated peroxide, then conditioned with a commercial conditioner. The hair that was bleached and not conditioned had 85% of the tensile strength of normal unbleached hair, while the hair that was beached and conditioned with a commercial conditioner had 88% of the tensile strength of normal hair. The addition of 10% phytosterol/octyldodecyl lauroyl glutamate to the commercial conditioner restored the hair to 93% of its original normal tensile strength. The addition of phytosterol/octyldodecyl lauroyl glutamate and amino acid derivative to a shampoo or conditioner restores chemically damaged hair nearly to its original pre-damaged state.

Sodium polyaspartate is another useful amino acid derivative to help mitigate hair breakage through the loss of tensile strength. Hair was permed as before with an ammonium thioglycolate solution neutralized with a sodium bromide solution. Tensile strength measurements were made on untreated haired, permed hair, and permed hair on which a 1.5% active tonic of sodium polyaspartate was sprayed. The results are evident on the following chart.

Figure 18

The permed hair treated with the sodium polysapartate solution had its tensile strength significantly restored.

Treating permed hair with an amino acid solution has been shown to improve the tensile strength at 20% extension measured in water. Hair again was permed in the usual way using a thioglycolate solution neutralized with sodium bromide and tensile strength measurements were made. Treating permed hair with histidine and also with phenylalanine improved the tensile strength of the hair to almost that of normal untreated hair.[24]

b. Dullness

Dull, lifeless hair is one sign of aged hair. Many materials have been added to conditioners, shampoos, and styling products to increase the sheen and luster of the hair to enhance an attractive look. Materials such as oils, esters, and silicones are commonly used and do a good job. The addition of amino acid derivatives can augment the positive effects on sheen and luster in the hair.

An amino acid cocktail composed of sodium PCA, PCA, sodium lactate, arginine aspartic acid, glycine, alanine, serine, valine, proline, threonine, isoleucine, histidine, and phenylalanine has been shown to increase the sheen and luster of hair.

Fig 19

The first tress is untreated hair, the second tress is treated with 2% of the amino acid cocktail, the third tress is treated with 5% of the amino acid cocktail.[25] As can easily be seen from the photograph In Figure 19 there is a dramatic enhancement of sheen and luster at the 2% level and a small gain at the 5% level over the 2% level.

The amino acid derivative lauroyl arginine, an amphoteric surfactant, has been shown to increase the luster of hair. In this case the lauroyl arginine helps align the hair fibers uniformly and reduces frizz. The more aligned hair fibers are more reflective as an artifact of the alignment increase in sheen and luster.

Fig. 20

The left side of the half-head is hair untreated with lauroyl arginine, which shows frizz and some dullness. The right side of the half-head is treated with lauroyl arginine, showing more uniformly aligned hair fibers and better luster. It should be noted that a combination of 1% amino acid cocktail mentioned previously and 0.1% lauroyl arginine in a conditioner have shown remarkable benefits in field tests where 68% of the subjects said that they saw an immediate improvement in their hair after one application.[26]

c. Elasticity

The ability of hair to bounce and move lends itself to a picture of youth and vigor. In the 1960s there was a TV commercial that depicted a young woman running through a pastoral field with her hair bouncing and swinging as she ran. This was supposed to depict the essence of beautiful hair.

A measurement of bounce is bending strength in which hair fibers are cleaned, then treated with conditioning agents, and a force is applied transversely across the fibers.

Method: Hair was washed with a SLES solution and then treated with a cationic surfactant solution. Bending strength was then measured 25C 40% RH.

Figure 21

STAC= Stearyl Trimethyl Ammonium Chloride
DSTMAC=Distearyl Dimethyl Ammonium Chloride
CAE=PCA Ethyl Cocoyl Arginate

The more force required to bend the fibers, the greater the bending strength and the greater the bounce. In the above chart, Figure 21, stearyl trimethyl ammonium chloride (STAC), and distearyl dimethyl ammonium chloride (DSMAC) are contrasted with the amino acid conditioning agent PCA ethyl cocoyl arginate (CAE). It is clear that the force required to bend the hair fibers treated with CAE is greater than that required to bend STAC- or DSMAC-treated fibers. The amino acid–derived conditioning agent provides more bounce to the hair. By combining materials such as this with those previously noted that increase the hair's tensile strength, there is a positive effect on hair elasticity.

d. Roughness

Smooth hair feels good to the touch and reflects light giving the hair good shine and luster as seen earlier. There are many materials that can be used to produce smoothness in the hair.

Hair was washed in a simple shampoo:

	%
SLES	15.0 active
Humectant	15.0 active
Water	qs to 100%

The humectants: 1,3 Butylene Glycol, Glycerin, PCA-Na

The hair was rinsed and allowed to dry at ambient

temperature and humidity.

- Sensory evaluation done n= 6

Figure 22

In this test the hair was washed with a simple sodium laureth sulfate shampoo and the shampoo in which humectants were added. The hair was then rinsed and allowed to dry at room temperature. Sensory evaluations were then conducted. Hair treated with glycerin and 1,3 butylene glycol produced a higher degree of roughness to the finger than the SLES-washed hair. Sodium PCA on the other hand produced a feeling of greater smoothness.

This can also be demonstrated using dynamic frictional coefficient measurements as in the following chart. "The dynamic coefficient of friction, also called the kinetic or sliding coefficient of friction, or friction coefficient (symbol μ or f, dimensionless), is a measure of how large the friction forces are which act between two solids."[27] In this case the hair is treated with the humectant and the combing force is measured via a rheometer.

Fig. 23

Hair was washed in a simple shampoo:

	%
SLES	1.0 active
Humectant	0–1.0 active
Water	qs to 100%

The humectants: 1,3 butylene glycol, glycerin, PCA-Na

The hair was rinsed and allowed to dry at ambient temperature and humidity.

Frictional coefficient was then measured.

Here again the hair treated with sodium PCA is much smoother than hair treated with either 1,3 butylene glycol or glycerin.

PCA ethyl cocoyl arginate has been shown to repair the cuticle smoothing the hair surface. This can be seen in SEM micrographs of damaged hair without and with CAE treatment.

Fig. 24

Top: SEM observation of a 1% SLES-washed and tied hair

Bottom: SEM observation of a 1% SLES-washed, 1% CAE-treated (dipped 4–5 minutes), tied hair.

CAE helps repair mechanical surface damage to the hair shaft.

Arginine is another useful amino acid to smooth the hair. In the following chart, hair was washed with 1% sodium lauryl ether sulfate and 1% sodium lauryl ether sulfate plus 0.1% arginine, all on an active-substance basis. The wet dynamic friction coefficient clearly shows that the hair washed with SLES and arginine is smoother than that washed with SLES alone.

Figure 25

Arginine is an alkaline amino acid and can be used to neutralize styling gel polymers. In the following series of tests, arginine is shown to have a positive effect on smoothness and texture of styled hair.[28]

4.3.4.4 FORMULATION FOR SKIN CARE

a. Cleansers

Facial Cream Cleanser

Ingredient	**% (w/w)**
Sodium Stearoyl Myristoyl Glutamate	20.00
Sorbitol	20.00
Stearyl Alcohol	1.5
Disodium Cocoamphodipropionate	5.00
Zinc PCA	0.10
Glycine	0.36
L-Proline	0.45
L-Alanine	0.15
Preservative	Qs
Deionized water	Qs

Combine ingredients except the sodium myristoyl glutamate with mixing and heat to 75°C. Slowly add the sodium myristoyl glutamate, maintaining temperature and controlled mixing. Mix until uniform at 75°C, then allow to cool to room temperature.

		Formulation No. 1	Formulation No. 2	Formulation No. 3	Formulation No. 4	Formulation No. 5	Formulation No. 6
Pemulen®* TR-1† (BF Goodrich)		0.50	0.50	0.50

	Dryness of the tip of hair	Less	Slightly less	Slightly less	Slightly less	Slightly strong	Strong

* : Condition of curling (National CURLUN 18 EH947 (Matsushita Electric Works Ltd.) (Curler: large (Blue))

Make a bundle of hair (about 2 x 4cm) of a constant volume using a wig, and apply 0.5g of the sample all over centering around the tip of hair. Immediately after application, curl the hair with a curler, allow to stand a room temperature for 20 minutes, remove the curler cautiously.

**: Condition at application to straight hair

Make a bundle of hair (about 2 x 4cm) of a constant volume using a wig, and apply 1.0g of the sample all over centering around the tip of hair. At this time, apply the sample while spreading so that the bundle of hair may be uniform straightly. After application, allow to stand at room temperature for 1 day and confirm the setting power, the smoothness of combing, etc.

Pearl Bath and Shower Cleanser

Ingredient	**% (w/w)**
Potassium Cocoyl Glycinate	30.00
Lauramide MEA	1.50
Lauramidopropyl Betaine	30.00
Propylene Glycol	1.50
Glycine	0.40
Amino Acid Cocktail (Sodium PCA, Glycine, Glutamic Acid, Alanine, Lysine, Arginine, Threonine, Proline, Betaine, sorbitol	0.55
Alanine	0.55
Sodium PCA	0.15
Glycol Distearate	1.00
Citric Acid (20% aq soln)	2.00
Preservative	QS
Deionized Water	Qs

Sebum Control Facial Cleanser

Phase	**Ingredient**	**%(w/w)**
A	Didodium Cocoamphdiacetate	8.00
	Lauryl Glucoside	9.00
	Disodium Cocoyl Glutamate and Sodium Cocoyl Glutamate	20.00
	Glyceryl Laurate	3.00
	Sodium PCA	2.00
	Zinc PCA	1.00
	Deionized Water	QS
B	Lauroyl Lysine	1.00
	Deionized Water	2.80
	Sodium Hydroxide, pellets	0.20
C	Preservative	QS
D	Citric Acid	To pH 5.7 +/– 0.2

Combine phase A and begin mixing and heating to 75°C. Carefully combine phase B mix until clear (pH should be > 13.3). When phase A is uniform, carefully add phase B to phase A, maintaining mixing. Cool to room temperature. Add phase C and adjust pH (phase D).

Cold Process Cream Cleanser

Phase	Ingredient	% (w/w)
A	Xanthan Gum	0.30
	Deionized Water	42.70
B	1,3 Propane Diol	28.00
	Glycerin	4.00
C	Lauroyl Lysine	0.50
	Sodium Hydroxide pellets	0.10
	Deionized Water	1.40
D	Sodium Myristoyl Glutamate	15.00
	Sodium Cocoyl Glycinate	5.00
E	Lauryl Glucoside	1.50
	Preservative	QS
F	Citric Acid	To pH 7.0 +/– 0.2

Combine phase A with mixing at room temperature until gum is completely hydrated and phase is clear and uniform. Add phase B to phase A. Carefully combine phase C and when clear and uniform (pH should be > 13.3) add to phase A. Add phases D and E. Adjust pH (phase F). Maintain controlled mixing throughout.

Pump Facial Cleanser

Ingredient	% (w/w)
Sodium Cocoyl Alaninate (30%)	30.00
Coco-Betaine	14.00
Disodium Cocoamphodipropionate	15.00
Sodium PCA	1.00
Zinc PCA	0.1
Glycine	0.36
Proline	0.45
Alanine	0.15
Preservative	QS
Deionized Water	QS
Citric Acid	To pH 5.7 +/– 0.2

Combine all ingredients with mixing at room temperature. Adjust pH.

b. Moisturizers

Facial Moisturizer

Phase	Ingredient	% (w/w)
A	Grape Seed Oil	7.50
	Sesame Seed Oil	3.00
	Isopropyl Lauroyl Sarcosinate	15.00
	Lauroyl Lysine	1.50
	Alpha Tocopherol	0.50
	Phytosterol/Octyldodecyl Lauroyl Glutamate	5.00
B	Deionized Water	QS
	Xanthan Gum	0.40
	C12-13 Alkyl Glyceryl Hydrolyzed Hyaluronate	0.10
	Perilla Seed Extract	0.10
	Litchi Seed Extract	0.10
C	Sodium PCA	1.00
	Zinc PCA	1.00
D	Sodium Stearoyl Glutamate	3.60
E	Preservative	QS
F	Citric Acid	To pH 5.5 +/– 0.2

Combine phase A ingredients at room temperature with stirring. Charge batch vessel with water of phase B and begin controlled propeller mixing. Dust Xanthan into phase B and allow to completely hydrate. When clear, add phase C and phase D to phase B. Add phase A to phase B, maintaining mixing. Add phase E. Adjust pH (phase F), all at room temperature.

Light Moisturizer

Phase	Ingredient	% (w/w)
A	Vegetable Oil	25.00
	Phytosterol/Octyldodecyl Lauroyl Glutamate	3.00
	Isopropyl Lauroyl Sarcosinate	10.00
	Lauroyl Lysine	5.00
	Tocopheril	0.50
B	Deionized Water	QS
	Xanthan Gum	0.50

Phase	Ingredient	% (w/w)
C	Sodium Steroyl Glutamate	2.60
D	Preservative	QS
E	Citric Acid	To pH 7.0 +/– 0.2

Combine phase A ingredients with mixing. Charge batch vessel with water phase B and begin propeller mixing. Slowly add Xanthan to water, maintaining mixing. When completely hydrated, add phase C to phase B. Add phase A to phase B, maintaining mixing. Add phase D to phase B and adjust pH (phase E), all at room temperature.

Lotion

Phase	Ingredient	%(w/w)
A	PEG-10 Hydrogenated Castor Oil	0.25
	PEG-20 Hydrogenated Castor Oil	2.25
	Phytosteroyl/Octyldodecyl Lauroyl Glutamate	1.00
	Mineral Oil	9.00
	Glycerin	10.00
B	Acrylates/C 10-30 Alkyl Acrylate Crosspolymer	0.5
	Deionized Water	49.50
C	Hydroxylethylcellulose	0.07
	Deionized Water	6.93
D	Arginine	0.40
	Deionized Water	3.60
E	Sodium PCA	1.00
	Amino Acid Humectant Cocktail: Betaine, Sodium PCA, Sorbitol, Serine, Glycine, Glutamic Acid, Alanine, Lysine, Arginine, Threonine, Proline	1.00
	Butylene Glycol	12.00
	Deionized Water	QS
	Preservative	QS

Dissolve part B and C respectively. Heat and mix part A to 80°C. Heat part B and C to 70°C. Add part B and C to A with agitation. Cool to room temperature with agitation. Add part D to ABC with agitation. Add part E to ABCD with agitation.

c. Serums

Phase	Ingredient	% (w/w)
A	Hydroxypropyltrimonium Hyaluronate	0.05
	Deionized Water	QS
B	Sodium PCA	1.00
	Amino Acid Cocktail: Sodium PCA, Serine, Glycine, Glutamic Acid, Alanine, Lysine, Arginine, Threonine, Proline, Betaine, Sorbitol	1.00
	Hydroylzed Hyaluronic Acid	0.10
C	Aloe Vera Extract	0.50
	Honeysuckle Extract	1.00
	Parsley Extract	1.00
	Rosemary Extract	1.00
	Green Tea Polyphenols	0.50
D	Preservative	QS

Mix phase A until dissolved; add phase B, then phase C and phase D.

Toner Mist

Phase	Ingredient	% (w/w)
A	Trehalose	0.25
	C12-13 Alkyl Glyceryl Hydrolyzed Hyaluronate	0.05
B	Deionized Water	89.30
	Glycerin	3.00
C	Amino Acid Cocktail: Sodium PCA, Sodium Lactate, Arginine, Aspartic Acid, PCA, Glycine, Alanine, Serine, Valine, Lysine, Threonine, Proline, Isoleucine, Histidine, Phenylalanine	1.50
	Saccharide Isomerate	2.00
	Extract mixture: Propylene Glycol, Water, Echinacea Angustifolia Extract, Centella Asiatica Extract, focus Vesiculosus Extract, Trigonella Foenum-Graecum Seed Extract	1.00
	Sakura Flower Extract	0.20

Phase	Ingredient	% (w/w)
	Bresenia Schreberi Leaf Extract	0.50
	Phenylehtanol, Ethylhexyl Glycerin	0.5
	Sodium Caproyl Prolinate	1.70

Combine phase B and add phase A ingredients in sequential order with thorough mixing until dissolved. Add phase C.

Facial Skin Toner

Ingredient	%(w/w)
Witch hazel Extract	25.00
Amino Acid Cocktail: Betaine, Sodium PCA, Sorbitol, Serine, Glycine, Glutamic Acid, Alanine, Lysine, Arginine, Threonine, Proline	1.00
Glycine	0.36
Proline	0.45
Alanine	0.15
Aloe Concentrate 40X	0.25
Chamomile Extract	0.29
e-Polylysine	1.00
Deionized Water	QS
Citric Acid	To pH 6.0 +/– 0.2

Combine ingredients at room temperature with mixing. Adjust pH.

4.3.4.5 HAIR CARE

a. Shampoos

Conditioning Shampoo with Water-Dispersible Lauroyl Lysine

INCI Name	*% w/w*
Ammonium Lauryl Sulfate	25.0
Sodium Laureth Sulfate	12.0
Disodium Cocoyl Glutamate and Sodium Cocoyl Glutamate	10.0
Glycol Distearate	2.5
Dimethicone	2.0
	3.0

INCI Name	*% w/w*
Cocamide MEA	1.50
Cocamidopropyl Betaine	7.0
Polyquaternium 7	1.0
PEG-80 Glyceryl Cocoate	1.0
Sodium PCA, Sodium Lactate, Arginine, Aspartic Acid, PCA, Glycine, Alanine, Serine, Valine, Lysine, Threonine, Proline, Isoleucine, Histidine, Phenylalanine	2.0
Lauroyl Arginine	0.1
Glyceryl Laurate	1.6
Zinc PCA	0.6
Phenoxyethanol and 3((2-ehtylhexyl)oxyl) 1,2-Propanediol	0.7
Aqua	Qs
Citric Acid	To pH 5.5

Combine all ingredients (except euxyl) with mixing while heating to 75°C. Allow to mix at 75°C for 15 minutes, then allow to cool to 50°C and add the euxyl. Continue cooling to room temperature while maintaining mixing. Adjust the pH with citric acid.

Powder Shampoo

INCI Name	*% w/w*
Sodium Lauroyl Glutamate	15.00
Sodium Myristoyl Glutamate	15.00
Lauroyl Lysine	1.00
Hydrolyzed Hyaluronic Acid	0.10
PCA	1.00
Talc	23.00
Sucrose	22.70
Maize Starch	22.00
Lauroyl Arginine	0.20

Combine in a tumble mixer.

Zinc PCA Shampoo

INCI Name	*% (w/w)*
Sodium Laureth Sulfate	35.0
Cocamidopropyl Betaine	15.0
PEG-7 Glyceryl Cocoate	2.0
Polyquaternium-7	0.2
Sodium PCA	2.0
TEA-Cocoyl Glutamate	16.0
Lauryl Lactate	1.5
	Qs
Aqua	QS
Zinc PCA	0.6

Combine all ingredients and adjust the pH with citric acid.

b. Conditioners

Natural Conditioner

INCI Name	*% (w/w)*
Isopropyl Lauroyl Sarcosinate	20.0
Lauroyl Lysine	2.0
Phytosterol/Octyldidecyl Lauroyl Glutamate	6.0
Vitis Vinifera (Grape) Seed Oil	6.0
α-Tocopherol	1.0
Aqua	Qs
Xanthan Gum	0.4
Lauroyl Arginine	0.2
Hydrolyzed Hyaluronic Acid	0.2
Sodium PCA, Sodium Lactate, Arginine, Aspartic Acid, PCA, Glycine, Alanine, Serine, Valine, Proline, Threonine, Isoleucine, Histidine, Phenylalanine	2.0
Sodium Stearoyl glutamate	5.0
Phenoxyethanol, 3[(2-ethylhexyl)oxy] 1,2-Propanediol	1.0
Citric Acid	Qs to pH 6.0 +/– 0.2

Charge batch vessel with water (phase b) and begin mixing. Slowly add remaining ingredients of phase B maintaining mixing and ensure complete hydration. Add phase C to phase B. Combine phase A in a separate vessel and add to phase B maintaining mixing. Add phase D. Adjust pH.

Leave On Conditioner

Phase	Ingredient	% (w/w)
A	Acrylates/C10-30 Alkyl Acrylate Crosspolymer	0.4
	Deionixed Water	39.60
B	Arginine	0.37
	Deionized Water	19.63
C	Butylene Glycol	3.00
	PEG-40 Hydrogenated Castor Oil	0.20
	PEG-40 Hydrogenated Castor Oil PCA Isostearate	0.20
	Phytosterol/Octyldodecyl Lauroyl Glutamate	0.05
	Isopropyl Lauroyl Sarcosinate	0.20
D	Dimethicone and Laureth-4 and Laureth-23	5.00
E.	Preservative	QS
	Alcohol	10.00
	Fragrance	QS
F	Amino Acid Cocktail: Sodium PCA, Sodium Lactate, Arginine, Aspartic Acid, PCA, Glycine, Alanine, Serine, Valine, Proline, Threonine, Isoleucine, Histidine, Phenylalanine	1.00
G	Disodium EDTA	0.02
	Deionized Water	QS

Dissolve part A and B separately with stirring at RT. Add part C to part A with stirring. Add part B to AC and heat to 60°C. Dissolve part D at 60°C, then add ABC to part D carefully and emulsify. Add part E with stirring. Cool to 50°C and add part F with stirring. Cool to 45°C and add part G with stirring.

CONCLUSION

Amino acids are very functional materials, both topically applied and through oral supplementation. The uses and patents of amino acids are growing year by year as can be seen from the following chart.

GLOSSARY

1. Corneocyte: An outer skin cell

2. Dynamic Frictional Coefficient: The dynamic coefficient of friction, also called the kinetic or sliding coefficient of friction or friction coefficient (symbol μ or f, dimensionless), is a measure of how large the friction forces are that act between two solids.

3. Keratolitic: The loosening or shedding of the horny layer of the epidermis.

4. Rheometer: An instrument for measuring flow, viscosity, and extensions of materials.

AHAS AND BEYOND: ANTI-AGING INGREDIENTS AND THEIR BENEFITS FOR ALL LAYERS OF THE SKIN

ABSTRACT

The alpha-hydroxy acids (AHAs), including glycolic acid, are ingredients that have revolutionized cosmetic anti-aging and are a critical part of the cosmetic chemist's formulary. This class of small organic acids has significant reparative effects to all layers of the skin, including exfoliation of the *stratum corneum*, increased epidermal keratinocyte proliferation and differentiation, modulation of melanin production, and increase to fibroblast production of dermal matrix components, resulting in clinically proven and consumer-recognized cosmetic benefits collectively associated with anti-aging.

Second- and third-generation hydroxy acids, including polyhydroxy acids (PHAs) and bionic acids (BAs), are not only milder having increased tolerability, but also impart protective effects such as barrier strengthening, antioxidant, and matrix metalloproteinase inhibition. More recently, acetylamino sugars and acetylamino acid derivatives have arisen from the AHA research. Many of these compounds are effective at higher pH, and like the PHAs, provide significant anti-aging benefits with inherent gentleness to the skin. Formulating with hydroxy acids represents a challenge to the cosmetic chemist, as there are nuances to formulating for efficacy without irritation, and in addition, low-pH emulsions can be difficult to stabilize. However, the challenges to formulating highly effective and stable topical products containing hydroxy acids and related compounds can be overcome through careful selection of vehicle components, including thickeners, emulsifiers, formula pH, and ingredient combinations.

This chapter provides an in-depth review of the evolution and discovery of the value of AHAs as uniquely powerful anti-aging ingredients. The in-depth review of the literature, combined with numerous clinical study results and the thoughtful description of the various mechanisms proposed, is compelling. Also of interest is the description of various cogent formulation approaches to maximizing efficacy while minimizing irritation.

4.3.5.1 INTRODUCTION

Improvement in the appearance of photo-aged skin continues to be a high priority among consumers. Photo-aged skin is the manifestation of accumulated skin damage from chronic sun exposure superimposed upon the chronological aging process. The appearance of photo-aged skin is typically defined by lines and wrinkles, irregular texture, loss of firmness and elasticity, and an increased amount and reduced uniformity of pigmentation. The alpha-hydroxy acids (AHAs) were initially discovered by Drs. Van Scott and Yu in the 1970s and found to be useful for their effects on normalizing hyperkeratotic conditions such as ichthyosis.[1] In the subsequent decades, the discoveries of the broad pleiotropic effects of AHAs on all layers of the skin resulted in an array of cosmetic clinical benefits that is unmatched in cosmetic skin care. Topical cosmetic formulations containing AHAs at low concentrations (4–10%) have been shown to improve the appearance of photo-damage by a number of quantitative clinical endpoints. Numerous investigations into the mechanisms of action of AHAs support that the cosmetic benefits are likely derived from their impact on the skin surface as well as well as stimulatory effects on keratinocytes and fibroblasts.

The first-generation AHAs gave way to second- and third-generation polyhydroxy acids (PHAs) and bionic acids (BAs), which impart comparable clinical benefits for amelioration of photo-aging to AHAs, with improved mildness and additional skin-protective effects. This stream of investigation led to the discovery of the anti-aging benefits of N-acetylamino sugars and N-acetylamino acids and derivatives. The majority of these compounds are physiologic, natural, and nontoxic. They normalize keratinization and skin structure. The compounds discussed herein have a marked effect on epidermal and dermal thickness, and stimulate dermal fibroblasts to increase synthesis of glycosaminoglycans and collagen. Those with multiple hydroxyl groups impart a humectancy benefit as well as antioxidant characteristics, and are ideal for cosmetic treatment of aging skin appearance. This latest generation of anti-aging ingredients are especially gentle, which makes them ideal for use on sensitive skin.

Successfully formulating with AHAs requires a multiplicity of considerations since the balance of efficacy and irritation can be dependent upon the type of formula employed (such as oil-in-water, water-in-oil, or water-in-silicone emulsions) and the desired pH. Further, other parameters to be considered are emulsifier

and thickener selection in order to ensure formula stability, and selection of co-actives, which work optimally at a given pH. Thus, the thoughtful formulator must balance a variety of critical parameters in maximizing performance of cosmetic formulations containing hydroxy acids.

4.3.5.2 ALPHA-HYDROXY ACIDS (AHAS)

Structural and Physicochemical Properties of AHAs

The AHAs are organic carboxylic acids, with the distinct feature of having a hydroxyl functionality group attached to the carbon unit adjacent (or in the alpha position) to a carboxylic acid moiety.

Figure 1: Alpha-Hydroxy Acid Chemistry

The AHAs are typically low-molecular-weight compounds with acidity that is modulated by the proximal hydroxyl group. AHAs are found naturally in many fruits, and have aptly been nicknamed the fruit acids.

The most commonly used AHAs in skin care today include glycolic acid, lactic acid, and citric acid. Glycolic acid, or 2-hydroxyethanoic acid, is the smallest of the AHA family, and is found in sugar cane juice. Glycolic acid has a molecular mass of approximately 76 daltons and a pKa of 3.8, approximately 1 unit lower than its non-hydroxy analog acetic acid. Lactic acid, or 2-hydroxypropanoic acid, is a 3-carbon AHA derived from milk. Lactic acid is endogenous to the body and is produced via metabolism and exercise, during which time pyruvate becomes converted by the enzyme lactate dehydrogenase. Several AHAs, such as lactic acid, have chiral carbon atoms, resulting in D and L stereoisomers. Citric acid is a polycarboxyl AHA, and is a unique hydroxy acid in that it has a hydroxyl group alpha to the 2-carboxylic acid moiety, and beta to the 1- and 3-carboxylic acid moieties. This structural configuration thereby makes it not only an AHA but also a beta-hydroxy acid (BHA).

Citric acid is naturally found in citrus fruits, and is also found in the body in the Kreb's (citric acid) cycle where it is critically involved in energy production. Citric acid also has antioxidant properties. These smaller AHAs are hygroscopic in nature and highly soluble in water. Mandelic acid, or phenylglycolic acid, is an aromatic alpha-hydroxy acid, and, as such, is considered a lipophilic AHA. As a lipophilic AHA, mandelic acid tends to not only possess anti-aging benefits, but has unique applications for oily and acne-prone skin due to the affinity of more lipophilic molecules to sebum.

Table 1: Alpha-Hydroxy Acids – Natural Occurrence and Properties

AHA	Occurrence	Structure	Molecular Weight
Glycolic acid	Sugar cane	$CH_2(OH)CO_2H$	76
Lactic acid	Sour milk, Tomato juice	$CH_3CH_2(OH)CO_2H$	90
Citric Acid	Citrus fruits, ie oranges and lemons	$HO\text{-}C(CH_2CO_2H)_2\text{-}CO_2H$	192
Malic Acid	Apples	CH_2CO_2H $CH(OH)CO_2H$	134
Tartaric Acid	Grapes	$CH(OH)CO_2H$ $CH(OH)CO_2H$	150
Methyllactic acid	Mangos	$CH_3\text{-}C(CH_3)(OH)\text{-}CO_2H$	104
Mandelic acid	Almonds	$C_6H_5CH(OH)CO_2H$	152

Discovery of AHA Benefits

The cosmetic uses of AHAs are said to date back to the times of Cleopatra, renowned queen of ancient Egypt, where the benefits of milk acids, later to be identified as lactic acid, were known at this early time for generating younger smoother skin. However, key scientific and clinical evidence for AHAs emerged in the 1970s when Van Scott and Yu discovered the effects of glycolic acid on normalizing skin keratinization dysfunctions in hyperkeratotic conditions such as ichthyosis.[1]

Through decades of clinical, histological, and cellular investigations, the beneficial effects of glycolic acid on *stratum corneum* desquamation and plasticization, epidermal proliferation and signaling, dermal matrix remodeling, and melanin production were discovered, providing strong support for the potential use of this compound for improving photo-aged skin. Initially the benefits of 25% glycolic acid for reversing both epidermal and dermal markers of photo-aging were demonstrated on photo-damaged forearms,[2] and subsequently the efficacy of lower-strength glycolic acid formulations were demonstrated.[3] *As a result, glycolic acid has become one of the most widespread cosmetic anti-aging ingredients used.*

4.3.5.3 QUANTITATIVE CLINICAL BENEFITS OF AHAS

The clinical benefits of topical cosmetic AHAs have been demonstrated in numerous randomized, double-blind, vehicle-controlled studies in both face[3,4] and photo-damaged arm[5,6] models. A few of the many clinical studies are described below.

The first such study of cosmetic strength AHAs was a 22-week, single-center study with both 8% glycolic and 8% L-lactic acid compared to a vehicle control.[3]

Products were applied monadically to the entire face and in paired comparison application to photo-damaged arms. Significant benefits to overall severity of photo-damage were observed with both glycolic and lactic acid compared to the vehicle control on the face and arm. Further, evaluation of the photo-damaged forearm provided greater sensitivity for differentiating individual aspects of photo-damage, such as the appearance of mottled hyperpigmentation, sallowness, and fine lines and wrinkles.

Another randomized, double-blind, vehicle-controlled face and neck 12-week application study compared a 5% unneutralized formulation of glycolic acid to its vehicle control.[4] In this study, the glycolic acid treatment showed significant improvement compared to the vehicle control in physician-assessed skin texture, and a strong trend for improvement to discoloration (composite score of melasma, solar lentigines, guttate hypomelanosis, poikiloderma) compared to the vehicle control.

Additional studies have shown benefits of AHAs in both paired forearm application and split-face application studies.[7-10] In addition to expert visual assessment of photo-damage, objective instrumental assessments have shown additional clinical benefits of AHAs compared to vehicle controls, and allow for sensitive measurement of their benefit at earlier time points. In 12-week photo-damaged arm studies,[5-7] healthy female subjects (n~20 per product application cell), ages 45–70 years old, with a moderate degree (grades 4–6 on a 0–9 scale) of photo-damaged skin on the forearms, were enrolled to participate in IRB-approved arm studies. Photo-damage on the forearms was defined by the appearance of "crepe-like" skin,[5] using a 0–9 scale (0 = none, 1–3 = mild, 4–6 = moderate, 7–9 = severe, with ½ point grades allowed). In addition, the arms were compared to obtain a directed difference assessment, using a 0–4 scale, of skin tone, dryness, crepey appearance, and overall photo-damage. The forearm studies were randomized 12-week, double-blinded, bilateral-paired comparison studies. Subjects applied 0.5 to 1.0 g of each product to the appropriate left/right forearm, twice daily for 12 weeks. Efficacy was assessed at baseline and after 4, 8, and 12 weeks of product application by an expert evaluator using the grading scales shown in Tables 2–4 below.

Table 2: Photodamage Intensity of Crepe-Like Appearance[5]

Numeric Grade	Category Grade	Descriptor
0	None	
1-3	Mild	Small circular fine lines; may not be obvious at first glance; see more with twisting of the skin; <25% of the lower outer forearm; usually not seen in the inner surface of the forearm
4-6	Moderate	Obvious lined pattern; may look like circular lines; may look 'puffy';> 25% coverage but not entire outer lower arm; usually seen on the inner forearm but to a lesser degree; full coverage near elbow regions, with extension of crepey pattern/lines toward the wrist
7-9	Severe	Up to 100% cover of the outer lower forearm: very obvious, well demarcated; long "puffy" (depth) longitudinal lines; inner covered

Table 3: Directed Difference Attributes for Photo-Damaged Arm Appearance[5]

Attribute	Descriptor
Crepe-like/crinkled	Loose surface, saggy/lined/wrinkled skin
Skin tone	Evenness of skin color; freckling; color of keratosis
Overall appearance	Global assessment of the condition of the area with respect ot texture, evenness of skin tone and overall surface featrues
Visual dryness	Scaling/flaking

Table 4: Directed Difference Magnitude for Photo-Damaged Arm Appearance[5]

Numeric Grade	Descriptor
0	No difference
1	Very slightly better
2	Slightly better
3	Moderately better
4	Much better

The benefits of 8% glycolic acid cream (pH 3.8) compared to a vehicle cream were assessed in repeated clinical studies using the Photo-Damaged Arm Model.[5] Improvement by glycolic acid to the crepe-like appearance of skin was statistically significant in 15 out of 16 clinical studies. The reproducibility of the magnitude of benefit imparted by glycolic acid was demonstrated within individual studies and across studies. In a similar study design, the significant improvement of an 8% glycolic acid (pH 3.8) compared to its vehicle cream was observed for crepe-like skin intensity (see Figure 2). Glycolic acid provided significantly greater improvement to crepe-like skin appearance than its vehicle after 8 and 12 weeks of use. This was also demonstrated using the directed difference evaluation of overall appearance and crepe-like appearance after 8 and 12 weeks of application, and continued improvement at 12 weeks of application. A trend was observed ($p<0.1$) for directed difference evaluation of skin tone (Figure 3).

Figure 2: Improvement (from Baseline) to the Intensity of Crepe-Like Appearance on Forearms: 8% Glycolic Acid Cream Compared to Vehicle

Figure 3: Directed Difference Evaluation of Photo-Damaged Arms: 8% Glycolic Acid Cream Compared to Vehicle

In split-face photo-damaged skin studies,[7-10] healthy female subjects, ages 30–70 years old, with moderate to severe overall facial photo-damage, were enrolled to participate in IRB-approved vehicle-controlled facial studies. Since subjects served as their own within-treatment control (e.g., applied both the AHA and vehicle cream to either side of their face), these studies required fewer subjects than monadic application studies, where independent groups of subjects evaluated either the test product or the control on the whole face. In addition, the introduction of noninvasive, objective instrumental evaluation to the clinical protocols allowed for more sensitive discrimination between the effects of the test products versus the vehicle, as well as detection of effects at earlier time points. Therefore these studies were typically a maximum of 12 weeks in duration, shorter than the earlier monadic studies, which were six months in duration.[3]

Photo-damage intensity on the face was assessed using validated expert visual scales. Subjects applied test products to their face, twice daily for up to 12 weeks. Assessment of skin condition (overall photo-damage, lines and wrinkles) was conducted by expert visual assessment and objective instrumental measurements were obtained at baseline and at monthly intervals.

In the photo-damaged facial studies, most study expert visual assessments were made using traditional photo-numeric 0–9 scales, where 0 = none, 1–3 = mild, 4–6 = moderate, and 7–9 = severe.[11–14] These scales are helpful for characterizing overall photo-damage as well as individual attributes of photo-damage, and assessments may be made using ½ point increments,[14] which allows for sensitive differentiation between technologies. In one study, 10 visual parameters were assessed using a physician global assessment scale, where 0=none, 1=mild, 2=moderate, and 3=severe. All ten parameters were summed to provide an overall score,

as well as a wrinkle and discoloration score (the sum of four out of ten parameters for each).[4]

In addition to visual assessment of photo-damage, objective instrumental assessment of skin improvement by AHAs included digital photography, ballistometry (elasticity and firmness), and 3D Cyberware™ facial scanning. The Diastron™ ballistometer is a pendulum-based, torsional instrument that can be applied to the skin at different forces, to measure initial indentation and rebound from the skin, as well as a measure of overall elasticity (damping coefficient, alpha). The 3D 3030/HIREZ Cyberware™ facial scanner uses a near-IR line projector attached to a cylindrical motion stage to compute 3-D depth information on the face in cylindrical coordinates (Figure 4). From these virtual scans of the face, the length, depth, and volumes of surfaces may be calculated. Since the development of this technique, there are now other commercially available 3-D face and body systems. Over time, these systems have continued to improve the resolution and photorealism of 3-D images.

Figure 4: Sample C3030/HIREZ Cyberware™ Facial Scanner Images

In a previously reported split-face and photo-damaged arm application study,[7] subjects applied an 8% glycolic acid cream (pH 3.8) compared to its vehicle. Ballistometer readings were collected at weeks 0, 4, and 8 using three different force settings. The ballistometer response curves were analyzed with digital filtering (Fast Fourier Transform methods) to remove noise, and then a genetic algorithm (GA) was used to identify features in the filtered response curves. Both the glycolic acid cream and vehicle cream improved skin elasticity at weeks 4 and 8. The GA was able to correctly classify an "active" response on the glycolic-treated side over a vehicle response in 17 out of 18 subjects, in both the face and arm treatment sites.

The 3-D depth and length of fine lines and wrinkles around the periorbital region were evaluated using the Cyberware™ 3030 HIREZ facial scanner in a split-face application study (P. D. Hawkins SS). An 8% glycolic acid cream (pH 3.8) was compared to its vehicle cream. Significant improvement to the length of fine lines was observed after four weeks of product application with the glycolic acid cream (Figure 5). The glycolic acid cream was statistically superior to the vehicle cream at weeks 4 and 8 for the length of fine lines and wrinkles, and at week 8

for the depth of fine lines and wrinkles. A sample baseline and week 8 image from the 2-D photographs is shown in Figure 6.

Figure 5: 3D evaluation of lines and wrinkles in the periorbital site using the Cyberware™ 3030 HIREZ facial scanner.

Figure 6: Left) Baseline; Right) After eight weeks of application using 8% glycolic acid cream (pH 3.8). After treatment, the fine lines and wrinkles are fewer and less deep in the periorbital area. The skin tone is also improved on the cheek, and the overall texture is smoother.

Consumers are also able to perceive the skin benefits imparted by AHAs over the vehicle controls. In a previously published report,[9] subjects viewed before and after photos in a randomized, double-blind 12-week multicell split-face application study. One of the treatment groups compared an 8% glycolic acid cream to its vehicle. Consumers evaluated their skin condition across multiple anti-aging attributes at the end of the study without using photos. Approximately three months later, subjects returned to view their baseline and week 12 photos, and were administered a similar questionnaire using the same attributes previously evaluated. Subjects were able perceive improvement to photo-damaged appearance, such as lines and wrinkles, evenness of color, and firm appearance, which were statistically significant in favor of the AHA cream compared to its vehicle.

The anti-aging benefits of AHA formulations over a vehicle control have been observed in multiple randomized, double-blind, vehicle-controlled studies. In both the split-face photo-damaged face and paired comparison arm models, improvement to appearance attributes has been observed for texture/lines and wrinkles as well as even tone/hyperpigmentation and overall appearance. These clinical changes correspond to the longer-term benefits observed in earlier six-month monadic use clinical studies, and translate to consumer perceived benefits, as observed in split-face application photo-damaged facial tests.

4.3.5.4 CELLULAR AND STRUCTURAL CHANGES ASSOCIATED WITH ALPHA-HYDROXY ACIDS

Several studies have been conducted to understand the modes of action by which AHAs provide their beneficial effects on skin. These studies have demonstrated that AHAs can have effects on all layers of the skin, starting with the outermost layer, the *stratum corneum*. The effects of AHAs extend through the viable epidermis, to the dermal compartment. *In vitro* studies have indicated that AHAs can have direct effects on multiple cell types present in the skin, including keratinocytes, fibroblasts, and melanocytes, which may explain, in part, the clinically observable effects on skin such as moisturization and improvement of photo-aging.

Effects of AHAs on the *Stratum Corneum*

Early studies by Van Scott and Yu[1,15] demonstrated that treatment of xerotic skin results in the normalization of *stratum corneum* (SC) exfoliation, increased plasticization, decreased formation of flaky scales, and a thinner, flexible, and more compact *stratum corneum*. An extreme example of this effect is seen in Figure 7, where thick scaly plaque skin treated with a combination of 20% alpha- and polyhydroxy acids (pH 3.8) provides a dramatic improvement to this condition.

Figure 7: Descaling effect observed with 20% AHA/PHA/bionic acid formulation: scaling on knee before (left) and after use (right)

One of the ways in which AHAs are believed to bring about these effects is by diminishing the adhesiveness of the corneal layer. AHAs are believed to modulate desquamation by altering or degrading corneosomes (desmosomes), thereby decreasing cohesion between corneocyte layers. There is general agreement that this action is restricted to the *stratum corneum*, but where exactly the AHAs exert their exfoliating effect in this epidermal layer remains unclear.

In low concentrations, for example 2–5%, glycolic acid is believed to facilitate progressive weakening of cohesion of the intercellular material of the *stratum corneum*, resulting in uniform exfoliation of its outermost layers, the *stratum disjunctum*. A study by Fartasch et al.[16] investigated the effects of topical treatment with a 4% glycolic acid formulation, pH 3.8, on the SC using electron microscopy. The lamellar body (LB) secretory system in the *stratum granulosum* (SG), and intercellular lipid lamellae in the SC in both vehicle and glycolic acid-treated samples were found to be comparable to normal human SC. The site of action of glycolic acid as applied in this study appeared to be the desmosomes.

Normally, progressive stages of degradation of the desmosomal plug are seen as a function of their precise location in the different SC layers.[17] The skin's natural degradation in the *stratum disjunctum* was accelerated in the glycolic acid-treated skin compared with vehicle-treated skin. Within the SC, enhanced desmosomal breakdown, promoting loss of cohesion and desquamation, appeared to be restricted to the *stratum disjunctum* while desmosomes of the *stratum compactum* were unaffected. In this study, glycolic acid appears to target the desmosomes without affecting the barrier structures of the *stratum corneum* since TEWL (trans-epidermal water loss) values remained unchanged. It also appears that lactic acid can stimulate ceramide synthesis,[18] which suggests that AHAs may provide improvement in skin barrier function.

Several hypotheses have been proposed with regard to the mechanisms by which AHAs affect the cohesion of the layers within the *stratum corneum* and enhance desquamation. AHAs could affect ionic bonding of the layers, inhibit enzymes such as sulfate and phosphotransferases, resulting in fewer electronegative sulfate and phosphate groups on the surface of corneocytes, thus diminishing

cohesive forces.[15] Enhanced desquamation may also be achieved via preferential acidification of the polar domains embedded within the hydrophilic lipid bilayers, or by activating by other means the acid proteases crucial for desmosomal degradation.[19] Human tissue kallikreins are a family of 15 trypsin- or chymotrypsin-like secreted serine proteases (KLK1–KLK15). Many KLKs have been identified in normal *stratum corneum* (SC) and are candidate desquamation-related proteases, particularly KLK-7.[20] AHAs could transiently change the pH of the corneum layers and activate these proteases, leading to corneosome dissolution. Topical application of a high concentration (50% @ pH 0.9) led to an initial inactivation followed by prolonged activation of cathepsin D-like protease in the upper layers. No changes in chymotrypsin-like proteinases were observed in this study.[21]

When applied to hairless mice, high concentrations of AHAs (70% glycolic acid) resulted in a loss of calcium gradient. This could lead to lamellar body exocytosis. An *in vitro* study using cultured keratinocytes suggested that glycolic acid could lower the calcium ion concentration, at least in part, through the chelating effects of the glycolic acid on the cationic ions.[22]

Effect of AHAs on the Epidermis

One of the most consistent effects observed following topical application of AHAs is an increase in viable epidermal thickness. Lavker et al.[23] reported that daily topical application of a 12% ammonium lactate formulation resulted in an increase in epidermal thickness. A thickened epidermis was also observed following 5% or 12% lactic acid application twice daily for three months.[24] Similar results were reported with a three-week application of glycolic acid.[25]

This change in the epidermis of skin could be a direct effect of AHAs on keratinocyte proliferation. When human epidermal keratinocytes were exposed to glycolic acid and L-lactic acid in cell culture, a stimulatory effect on keratinocyte proliferation was observed. The results of these studies indicated that both glycolic and lactic acids are mitogenic in nature as each significantly stimulated proliferation of keratinocytes compared to control cells.[26]

Effect of AHAs on the Dermis

In addition to the effects on the *stratum corneum* and the viable epidermis by AHAs, beneficial changes in the dermis have also been reported in multiple studies. These effects include a marked increase in glycosaminoglycans (GAGs), collagen, and dermal thickness. The studies described below used a range of concentrations of AHAs, starting from 4% to up to 50% and at varying pHs. Lavker et al.[23] demonstrated that 12% ammonium lactate, applied to normal skin in an open (four weeks) or occluded (three weeks) manner, resulted in a striking deposition of GAGs in the dermis. This AHA preparation also spared the atrophic effects of corticosteroids on the epidermis and dermis when applied in combination with clobetasol propionate.

In addition to GAGs, increased deposition of collagen has also been observed following application of AHAs. Smith et al. reported that treatment with 12% lactic acid resulted in increased epidermal and dermal firmness and thickness. This was accompanied by clinical improvement in skin smoothness and in the appearance of lines and wrinkles. In the same study, a lower concentration of AHA, namely 5% lactic acid, modulated surface and epidermal changes but no dermal change.[24]

In another study, 4% glycolic acid, pH 3.8, in a suitable formulation, was applied to forearms of ten subjects for three weeks under semi-occlusive conditions (five patches/week for three weeks). Biopsies were collected at the end of three weeks and samples were analyzed for viable epidermal thickness, pro-collagen 1 by immunohistochemistry, total collagen (Masson trichrome stain) and GAGs (colloidal iron). Four out of ten subjects showed an increase in viable epidermal thickness and in colloidal iron staining and seven out of ten showed increases in pro-collagen 1 as well as total collagen.[27] Representative images are shown in Figures 8–11.
